THE SOLID STATE

Debye-Scherrer Powder Diffraction using 55 Fe K X-rays on Lithium Fluoride

POWDER and single crystal diffraction of X-rays obtained from radioactive isotopes has been reported by this laboratory¹⁻³. The source was cyclotron-produced ⁵⁵Fe, laid down in a linear array on a platinum disk¹ (Fig. 1). Photons studied were the K_a X-rays from ⁵⁵Mn, the stable daughter product. The activity of the source was 100 mc., but this was reduced to about 19 mc. by self-attenuation and further reduced to about 13 mc. by natural decay at the time of this work. Experimental geometry used was that of the conventional diffractometer. Detection was by a proportional counter and relatively sophisticated electronics. Other workers (with the loan of this 55Fe source designed by this laboratory for use in the work reported) later also observed the more intensely diffracted beams from metallic (iron foil) samples4.

Concurrently, in Russia, Lobov and co-workers reported on film recording with an 55 Fe source in a Preston camera $^{5-7}$ of $25\cdot 4$ mm diameter. Their reported diffraction samples have all been metals, lead, copper and stainless steel, with the patterns describing the backscatter region and exhibiting one or two lines in evidence. Lobov's 55Fe source was produced by a reactor and was therefore contaminated with 59Fe as well as 54Mn, their gamma rays presenting, unfortunately, a serious film fogging problem.

A preliminary consideration was made of the relative source strengths, carrier-free character and potential

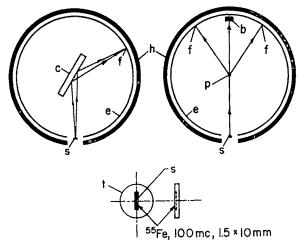

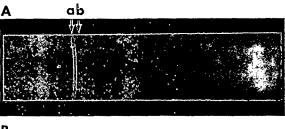

Fig. 1. The two geometries (single crystal (c) and powder (p)) used in this diffraction study. The linear **Fe source (s) is positioned, in both cases, within shielding, coincident with the circle defined by the emulsion (e). The focal point on the emulsion is indicated by (f). The emulsion (e) is mounted in a groove in the brass film housing (h). The **5Fe is laid down in a linear array 1-5 mm by 10 mm in a shallow recess in a 19 mm diameter platinum disk (t). The powder sample (p) is housed in a thin-walled glass capillary. The principal beam stop is at (b). A slit collimator, adjacent to the source (not designated), constrains the manganese K X-ray beam into a slightly divergent flat sheath; 2 mm wide at the sample and 4 mm at the beam stop.

exposure intensities. It was concluded that, with our uncontaminated, more intense 55Fe source, improved diffraction pattern recording by film exposure would be possible; and, more importantly, that nonmetallic powder samples might be analysed. A small (50.8 mm diameter) Debye-Scherrer camera was therefore designed and constructed.

The camera (Fig. 1) was constructed of brass. It consists of three parts: the base plate, with a centrally raised platform for the diffraction sample; the film housing, which fits on the base and is free to rotate through 360° about the stationary base; and the source holder and beam collimator, which fit into the film housing and turn with the film relative to the base plate, thus allowing for relative motion of the source and film with the sample. The source, when in place, is coincident with the diffraction circle. A slit collimation system is mounted in front of the source and inside the film circle. The collimator is 1 mm × 10 mm by 11 mm long. Its aperture is 14.4 mm from the centre of the system. The film fits in a recess around the inside of this housing.

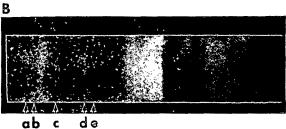

Fig. 2. A, A diffraction pattern of the 200 plane of a single lithium fluoride crystal produced by exposure for 2 h to the 13 mc. ⁵⁵Fe source in the camera previously described. a is the reflexion of the K_{α} doublet and b is the reflexion of the K_{β_1} radiation. B, A diffraction pattern from lithium fluoride powder produced with exposure for 118 h. The diffracted lines are identified as the reflexion of the K_{α} doublet on the following planes: a, the 222 plane; b, the 311 plane; c, the 220 plane; d, the 200 plane; and e, the 111 plane.

A single lithium fluoride crystal (Harshaw Chemical Co., Cleveland, Ohio) and 200 mesh lithium fluoride powder were selected as standards for the investigation. The preliminary studies carried out with the single lithium fluoride crystal immediately demonstrated photographic evidence of diffraction (Fig. 2A). The crystal was aligned to allow for diffraction from the 200 plane, and an exposure time of 2 h was used. The film was then developed for 4 min at 68° F in Kodak rapid X-ray developer and fixed in Kodak X-ray fixer. The emulsion was Kodak X-ray 'No-Screen'. The strong line is due to manganese K_a on the 200 plane, the weaker line is due to manganese K_{β_1} on the 200 plane.

After this single crystal success, lithium fluoride powder was mounted in a thin-walled (0.01 mm) Lindemann glass capillary with an inside diameter of 1 mm. The capillary was then mounted in a vertical position at the centre of the camera. The powder pattern obtained after exposure for 118 h is shown in Fig. 2B. Five of the diffracted lines caused by the K_a X-radiation of manganese are evident. The characteristic feathering of the line is due to the slit collimation. Developing procedures were the same as before. The various lines are identified in the caption.

These diffraction patterns obtained without the benefit of special intensification or developing techniques prove that recording of powder diffraction, by means of ordinary emulsion, is possible with an ⁵⁵Fe source of relatively low intensity. The exposure times used for the single lithium fluoride crystal (2 h) are in the range of practical work. The times necessary, however, for the powder diffraction patterns (118 h) are longer than desired. For both sample types, improved resolution would also be desirable, but analytical determinations can be made from the present data.

In order to see to what extent these conditions could be improved, a much more intense 55Fe source was studied (500 mc.) which had a self-attenuation of only about 25 per cent, compared with the 81 per cent for our source. On the basis of this comparison, it was found that an intensity improvement factor of 50 is currently obtainable. With such a source therefore exposure times could be reduced drastically or diffracted line width reduced appreciably. There is good evidence that the total output of such a source could be made still greater. In addition, the camera can obviously be made more efficient with a vacuum facility. Refinement in the alignment of this laboratory model is important and improvement is possible. It therefore seems that a zero power diffraction system of this type can be made truly competitive with standard techniques, especially where weight, portability, stability and power requirements are critical and are to be optimized.

We thank Jonathan Parsons for help in the development and densitometry of the diffraction patterns, G. Bartrum for the construction of the camera, and A. L. Klascius, Jet Propulsion Laboratory, for lending the 500 mc. source.

Strain Polarizability Constant: a Measure of Ion Overlap in Crystals of Sodium Chloride Structure

It is well known that when a cubic crystal of sodium chloride structure is stressed the refractive index changes and is different in different directions. Mueller¹ pointed out that the observed difference between the refractive indices for mutually perpendicular directions—that is, along the direction of stress and a direction perpendicular to it—is always smaller in magnitude, and for some crystals even different in sign, than the calculated one. He explained this discrepancy by assuming that the polarizability of an ion changes with the application of stress. If a hydrostatic pressure is applied, the change in the polarizability is represented by the strain polarizability constant λ_0 . From the data then available Mueller assumed that λ_0 is constant for all the crystals.

Burstein and Smith² pointed out that λ_0 is not a constant but varies from crystal to crystal. They also pointed out that λ_0 is a measure of ion overlapping and homopolar bonding in the stressed state. According to them, the magnitude of λ_0 depends on the initial amount of overlapping and homopolar bonding present in the crystal. The larger the amount of overlapping in the unstressed state, the greater will be the value of λ_0 in the stressed state. As examples, they mentioned lithium fluoride and magnesium oxide.

The aim of this communication is to show that λ_0 is a measure of ion overlap even in ionic crystals of sodium chloride structure other than lithium fluoride and magnesium oxide.

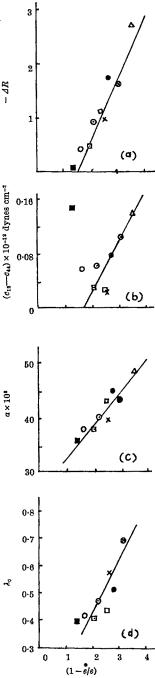

Fig. 1. $(1-\frac{e}{e}/e)$ versus (a) change in the molar refractivity ΔR , (b) difference between the elastic constants c_{17} and c_{44} , (c) coefficient of thermal expansion a, and (d) strain polarizability constant λ_{e} , respectively. \times , Sodium chloride; \otimes , sodium bromide; \triangle , sodium iodde; \bigcirc , potassium chloride; \bigcirc , potassium bromide; \bigcirc , potassium ioddide; $\boxed{\times}$, rubidium chloride; \bigcirc , rubidium bromide; $\boxed{\square}$, rubidium iodde.

Szigeti³ pointed out that Born's equation for the difference between the static and optical dielectric constants, which is based on the assumption of non-deformable and non-overlapping ions, is not in agreement with the observed values. In order to explain the discrepancy, he introduced the concept of "effective" ionic charge & which is less than e. He assumed that the electron cloud of the ions becomes distorted when these ions are in the solid state.

The magnitude of the electron charge, which resides in the distorted and overlapping regions, contributes to the homopolar bonding4,5, thus reducing the ionic strength of

the alkali halide crystals. Recently, Sirdeshmukhe, using the concept of effective ionic charge, showed that Megaw's relation for thermal expansion is valid for some of the alkali halide crystals.

It is well known that when ions change their state, that is, when they go from the gaseous state to the solid state, the molar refractivity changes and a deviation from the additive law is observed. The existence of non-central forces is represented by the fact that the elastic constant c12 is not equal to c_{44} . Similarly, Megaw's relation between thermal expansion and electrostatic share for alkali halides fails if the normal electronic

charge e is used. All these observations can be explained on the basis that part of the charge which resides in the distorted and overlapping region is responsible for the deviations. In order to show this, graphs have been plotted showing how the change in molar refractivity ΔR , the difference between the elastic constants $(c_{12}-c_{44})$, and the thermal expansion α , vary with the electric charge $(1 - \dot{e}/e)$, and are shown in Figs. 1(a), 1(b) and 1(c), respectively. These graphs clearly show that the change in the molar refractivity ΔR while going from the gaseous state to the solid state, the difference between the elastic constants c_{12} and c_{44} , and the thermal expansion of the alkali halide crystals increase with the decrease of the effective charge e.

In view of these observations, the strain polarizability constant of some of the alkali halides is plotted against (1 - e/e) and is shown in Fig. 1(d). This graph suggests that as the charge in the distorted and overlapping region increases, λ_0 increases. It means that the variation in λ_0 from crystal to crystal is an indication of the amount of ion overlapping present in these crystals in an unstressed state. This conclusion is in agreement with the views expressed by Burstein and Smith2.

Values of molar refractivity, elastic constants, thermal expansion, effective charge and λ_0 are taken from different sources and are listed in refs. 7–13.

PHYSICS

Interaction of Self-trapped Light Beams

PRELIMINARY experiments have been carried out on the interaction of two self-trapped light beams in water. The 200 MW, 20 nsec output from a Q-switched ruby laser* was split by prisms and focused into a glass cell containing water to form two self-trapped beams (Fig. 1). Photographs were taken using the light scattered sideways from these beams.

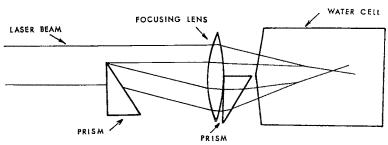

Fig. 1. Optical system used to produce two crossing self-trapped light beams.

Two types of scattering from self-trapped beams were observed; type A occurred when high purity water was used; type B was only produced in water which had been allowed to stand in an uncovered cell. When type A scattering was observed, the beams were characterized by fineness, short length, sharp cut-off and a tendency to scatter from a large number of discrete centres along the beam (Fig. 2). When type B scattering was observed, the beams were much longer than those associated with type A and the scattered light was much more diffuse, so that it was not always clear whether self-trapping had occurred (Fig. 3).

Fig. 2. Interaction of two crossing "type A" self-trapped beams. ($\times 1$.)

The apparatus used introduced distortion into the lower focused beam. The higher and lower edges of this beam were more intense than the centre, particularly the lower edge where self-trapping appeared to occur before the focal point was reached. Beyond the focal point two self-trapped beams were observed. The stronger beam travelled straight out from the end of the cone while the weaker appeared to be a continuation of the self-trapped lower edge of the cone. The weaker beam, after splitting from the stronger at the focus, bent and continued parallel

Using the optical system shown in Fig. 1, the interaction of the two crossing light beams was observed. In the case of type A scattering, interaction was shown as an intense

*Ruby laser Bradley type LH 351, delivering 200 MW in 20 nsec distributed among a number of transverse modes (between 1 and 8). Beam divergence, 8 milliradians.

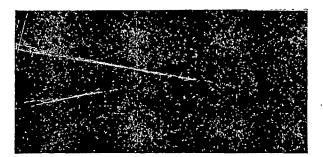

Fig. 3. Interaction of two crossing "type B" self-trapped beams. (×1.)

spot at the cross-over point (Fig. 2), but no significant effect on the beams could be observed because their scattering was not uniform. In the case of type B scattering, however, a considerable reduction in the intensity of the upper beam was always observed (Fig. 3). It is possible that this upper beam was not self-trapped, in which case interaction was between a high intensity light beam and self-trapped light. A considerable amount of energy was lost by the upper beam. This could have been reflected into the liquid or back along the pipe by the reflexion coefficient of the cross-over point, or could have been converted into shock energy. Whatever the mechanism, it is notable that the loss occurred only from the upper beam.

Observations on the Shape of Chromium Oxide Particles in Hydrogen+Oxygen+Nitrogen Pre-mixed and Diffusion Flames

CERTAIN metals, when introduced into pre-mixed, hydrogen + oxygen + nitrogen flames ($T \sim 2,000^{\circ}$ K) burning above a Meker type burner, give a whitish, streaky appearance to the flame¹. Such streaks appear, for example, when chromium, vanadium, titanium, cobalt, nickel or iron (to mention but a few) are introduced in the form of fine sprays of dilute salt solutions. These streaks almost certainly originate from chemiluminescent reactions involving H and/or OH radicals on the surfaces of particles of involatile oxides¹, and their visible appearance alone clearly indicates that the particles consist of many molecular units. Light scattering and electron microscopy studies^{2,3} have shown similar particles to have sizes in the range $0.005-25\mu$.

An interesting effect observed—or rather heard—in such systems, with concentrated (~molar) aqueous solutions of chromic acid is a quiet but distinct decrepitation. This phenomenon could well arise as a side-effect of the manner in which these particles disintegrate in the flame, and what follows might reasonably be interpreted to support such a view.

Electron microscopy of carbon-coated copper grids passed through pre-mixed flames into which chromic acid had been sprayed revealed irregularly shaped particle fragments, of average size 50–100 Å. Similar experiments in diffusion flames, however, revealed larger fragments, and occasionally it was possible to pick up large, perfectly spherical particles like that shown in Fig. 1. Moreover, such particles were clearly hollow, and equally clearly

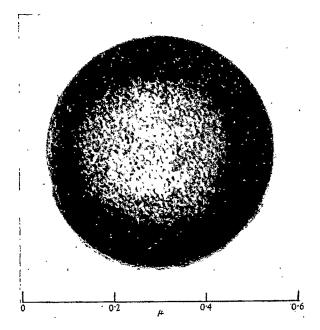

Fig. 1. Chromium oxide particle in hydrogen diffusion flame.

much of the debris on the grid originated from such hollow spheres.

Particles of size $\sim 1\mu$ (Fig. 1) contain the same number of chromium oxide molecules as would be present in an aqueous droplet of M chromic acid approximately ten times the particle in diameter. This predicted value of 10μ for the droplet size agrees very well with the size measured experimentally under comparable conditions⁴. Previous work in another context¹ has also shown that water droplets, once formed at the atomizer, do not significantly coalesce in the time taken (0.5 sec) to reach the flame, and it is therefore clear that each sphere observed on the grid represents molecules present in a particular water droplet at the instant of droplet forma-

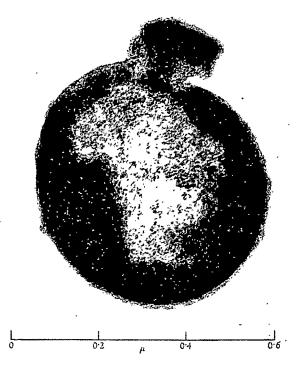

Fig. 2. Chromium oxide particle in hydrogen diffusion flame.

tion. If this were the case, then lowering the surface tension of the atomizer solution should cause the particle size to decrease; this effect has also been observed in the present work in experiments in which the chromic acid was made up in acctone and water mixtures.

The fate of a droplet bathed in flame gases may be visualized as one of rapid contraction of a spherical shape, the centre at least of which may retain a trace of solvent until contraction can no longer take place. At this stage, the temperature of the surface rises particularly rapidly by both physical and heterogeneous chemical processes, causing the particle to solidify, melt or vaporize (depending on temperature). Decrepitation might then result if the last traces of solvent were to cause particles which are molten on the surface to explode. Fig. 2 shows strikingly such a particle at the instant of disintegration.

We thank Dr R. P. Ferrier, of the Cavendish Laboratory, Cambridge, for helpful advice on electron microscope techniques. The instrument used was an AEI, type EM6, made available by the Department of Metallurgy.

Amplitudes are half the peak to peak displacement.

The experiments consisted essentially of establishing a given flow condition without vibration and measuring the discharge, pressure drop and temperature for that condition. Then, a programme of transverse vibration was followed noting the changes, if any, in the quantities. No changes were observed for any flow condition (except in a series of tests with water at Reynolds numbers above 2,200, as already noted). A typical set of data for aircraft hydraulic oil (AN-O-366) is quoted in Table 1 and vibration conditions are described in Table 2.

Comments on Effect of Vibrations on the Transition Regime in Pipe Flow

The results recently reported by James and Morton¹ disagree with results which I obtained in 1951 in research supported by the US Office of Naval Research. My work actually covered the effects of transverse and longitudinal vibrations on flow in circular tubes over a range of Reynolds numbers from 750 to a little more than 10,000, including the transition regime. I concluded that vibration had no effect on the friction factor except that at Reynolds numbers above about 2,200 flow which was laminar without vibration became turbulent with certain types of vibration. (Laminar flow was obtained to a Reynolds number of about 15,000 in the apparatus using a special head tank and water as fluid.)

My tests in the transition regime delineated by James and Morton were made in an aluminium alloy tube (12 ft. long, 0.5 in. outside diameter, 0.065 in. wall thickness), using chiefly aircraft hydraulic oil as fluid. The tube was clamped near both ends to give fixed end conditions about 9 ft. 2 in. apart. Piezometer taps were located 11.5 ft. apart, outside the clamps. The taps were carefully deburred by reaching in from the ends of the tube. An entrance length of about 30 in. was joined smoothly to the upstream end. A heat exchanger was provided to

maintain constant temperature.

CHEMISTRY

Variations in Ozone Formation across the Ozonizer Discharge Gap

I have studied, by means of the planar ozonizers with quartz windows, described previously1, the variations in the formation rate of ozone in the discharge gap. Double-glass and metal-glass ozonizers with 3 mm gaps were used with dried air and oxygen at a pressure of 760 mm of mercury and in the temperature range 20°-25° C.

A beam of radiation of wavelength 2537 Å, which is heavily absorbed by ozone, traverses the discharge gap with its axis parallel to the ozonizer electrodes, and a movable slit, 0.16 mm wide, selects the radiation which has passed through a known region of the gap. This radiation reaches a quartz-window photomultiplier with a dielectric filter transmitting at 2537 Å and the output voltage of the photomultiplier controls one beam of a cathode ray oscillograph to indicate ozone concentration in the chosen region. A single-shot time base is used which is triggered either by the discharge or a few milliseconds before discharge. The other beam indicates the ozonizer current; typical oscillograms are shown in Fig. 1. The first three half-cycles of a discharge are usually unsteady, and in deducing formation rates later half-cycles, usually from the sixth to the twelfth, were used. To find the formation rate in a half-cycle from the oscillogram, a correction for diffusion is made by using the slope in the quiescent part of the half-cycle. A correction is also

^{*}Determined by Engler viscosimeter at atmospheric pressure and corrected to mean pressure by adding 1.5 per cent for each 100 lb./in.² above atmospheric pressure.

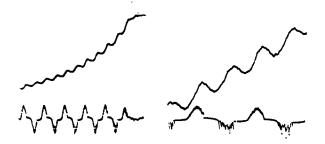

Fig. 1. Oscillograms of photomultiplier output (upper trace) against ozonizer current. Time increases from right to left. The oscillograms are for a distance of 0-20 mm from the glass wall of an aluminium-glass ozonizer using oxygen at 160 c/s. The first shows the first eleven half-cycles of a discharge, while the second shows only the seventh to the tenth half-cycles of another discharge.

necessary for the varying concentration of ozone across the ozonizer at the chosen half-cycle and when air is used a small correction is necessary for radiation from the discharge. The metal-glass ozonizer had an active area of 6.35 cm², the metal being aluminium and the dielectric soda glass 1.30 mm thick. Plates of the same thickness were used in the double-glass ozonizer. The frequency of the supply voltage was 160 c/s and the currents used were from 500 to 1,200 μamp for the metal-glass ozonizer and from 100 to 200 µamp for the other.

The results (Fig. 2) were unaffected by the intensity of the ultraviolet beam or the current density. Increasing the supply frequency to 300 c/s produced no changes and measurements at 50 c/s were consistent with those at 160 c/s when allowance was made for the much larger diffusion effects.

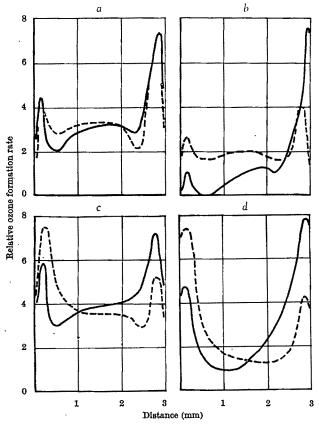

Fig. 2. Relative ozone formation rate against distance from the lower wall of the discharge gap. The full line refers to the upward half-cycle, when electrons and ions are moving away from the lower wall, which is the metal one for the aluminium-glass ozonizer. The broken line is for the downward half-cycle. The currents differ for the four pairs of curves. Aluminium-glass ozonizer: a, oxygen; b, air. Double-glass ozonizer: c, oxygen; d, air.

The results for both ozonizers and gases show clearly that the ozone formation rate varies greatly across the discharge gap, which is important when deducing from ozonizer characteristics the reactions leading to ozone formation^{2,3}. The accuracy of the relative formation rates is about ± 25 per cent near the main peak for all curves and elsewhere it is ± 0.4 for oxygen and ± 0.6 for air in the metal-glass ozonizer and ± 0.6 for oxygen and ± 0.8 for air in the double-glass ozonizer. A noteworthy feature is that, in a metal-glass ozonizer using air, 50 per cent more ozone is formed on the downward half-cycle compared with the upward. This was checked by illuminating the gap uniformly and detecting all the emergent radiation. The same charge passes in both half-cycles, for tests on the ozonizer current showed that no rectifier action occurs. Experiments with fused quartz as the dielectric, in the metal-glass ozonizer using oxygen, gave similar curves to those shown, but the main peak near the dielectric was 25 per cent stronger on the upward curve than on the downward. The use of borosilicate glass reduced the peaks near the metal to the same height as the central region, but the intervening minima were preserved and elsewhere the curves were the same as for soda glass.

The location of ozone formation has been discussed by various authors^{2,4,5}, but no detailed theory has been attempted and no direct results have been reported. The curves given are for formation rates averaged over a halfcycle. It seems reasonable to expect that the curves for the electrostatic field, averaged over the active part of the half-cycle, will bear a general resemblance to those for ozone formation and that large potential drops therefore occur at the sites of the large formation peaks. In the upward discharge of a metal-glass ozonizer, using oxygen, there are thus two regions of marked potential change corresponding to the cathode fall and anode fall in a lowpressure glow discharge. The anode fall of the former discharge indicates the presence of large space charges, and while these may be caused by the ready formation of negative ions in oxygen a more important agent may be the backscattering of ions and electrons at the dielectric surface. The differences in the air curve compared with the oxygen curve may then be explained as being caused by the stronger backscattering of electrons at the dielectric surface. The large anode fall in the upward discharge in air means that many of the electrons and ions are generated near the anode and that, while the same charge is passed as in the downward half-cycle, more energy is now given to the positive ions, which produce no ozone, and consequently much less ozone is produced in this half-cycle.

Total Ionization Cross-section of some Tetra Alkyl Metal Compounds

One of the conclusions of a preceding paper was that the dissociation energy of the metal-carbon bonds decreases with the increasing mass number of the metal atom in the series (Alkyl)₄C, (Alkyl)₄Si, (Alkyl)₄Ge, (Alkyl) Sn and (Alkyl) Pb, where Alkyl is CH3 or C2H5. This we attributed to the increasing bond polarizabilities.

According to Lampe *et al.*², there is a linear relationship between the polarizability and the total ionization cross-section. This relationship can be rationalized theoretically as follows.

The static polarizability for an atom is, according to Slater³,

$$\alpha = \frac{2}{h} \sum_{a} \frac{|M_{a_0}|^2}{v_{a_0}} \tag{1}$$

(2b)

where $|M_{a_0}|$ is the a_0 'th element of the dipole moment matrix and v_{a_0} is the frequency corresponding to the transition between the states 0 (ground state) and a.

Using the Bethe-Born approximation, Mott and Massey⁴ derived an expression for the atomic ionization cross-section

$$Q^{i}_{nl} = \frac{2\pi e^{4}}{mv^{2}} \frac{c_{nl}}{|E_{nl}|} Z_{nl} \log \left(\frac{2mv^{2}}{c_{nl}}\right)$$
 (2a)

$$c_{nl} = (Z^2_{\text{eff}}/n^2 a_0^2) \int |X_{nl,K}|^2 dK$$

The integration in equation (2b) is carried out over the appropriate portion of the ionization continuum. The matrix element $|X_{nl,K}|$ will be proportional to the corresponding dipole moment matrix element $|M_{nl,K}|$, and to the extent that the variation in $\Sigma(M_{a0}^2/\nu_{a0})$ parallels

that in $c_{nl}/[E_{nl}]$ in going from one atom to another, a linear relationship between polarizability and cross-section should be observed.

Lampe et al. expect that analogous expressions should apply to molecules. In order to check the correlation of the bond polarizability with the behaviour of the metal organic compounds under electron impact, we measured the total ionization cross-sections of the compounds mentioned.

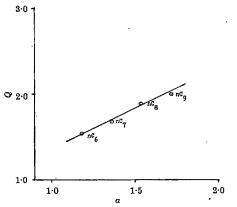

Fig. 1. Total ionization cross-section (Q) against polarizability (a) of some normal alkanes in arbitrary units.

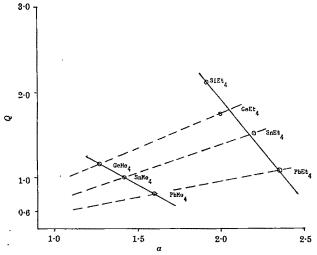

Fig. 2. Total ionization cross-section (Q) against polarizability (a) of some metal organic compounds in arbitrary units.

The cross-sections were measured on an AEI M.S.9 mass spectrometer under the following conditions: electron accelerating voltage 50 V; electron current $100~\mu A$; and temperature $230^{\circ} \pm 5^{\circ}$ C. Ion currents were read from the monitor when a known amount of sample has evaporated completely in the heated inlet system of the mass spectrometer. Cross-section values are normalized to the value for n-hexane.

In order to test the method, the cross-sections of some alkanes were measured and the relationship with the polarizability is shown in Fig. 1. The polarizabilities have been calculated from the molar refraction coefficients.

There appears to be a good linear relation between the total ionization cross-section and the polarizability, and these data fit in with the theory of Lampe *et al*.

In Fig. 2 the relative values of the total ionization cross-sections of the tetra alkyl metal compounds are plotted against the polarizabilities. Here the tendency is the opposite of that predicted by theory, although the relationship is again linear.

The cross-sections decrease with the increasing polarizabilities of the metal atoms, although they still increase with increasing polarizabilities of the alkyl groups.

We must conclude that the theory which was developed for atoms and which so far has seemed acceptable for dealing with molecules may only be applied for the comparison of molecules of closely related structures. Its limits have been reached with the introduction of metal atoms into organic molecules.

Kinetics of Ligand Exchange in a Europium Complex

We have previously reported the synthesis of 4,4'-di-n-butyl-2,2'-bipyridyl (L) and its complexes with lanthanide nitrates. We now find that the complex $[\mathrm{Eu}(\mathrm{NO_3})_3L_2]$ in chloroform solution undergoes fairly rapid exchange with added free ligand

$$[\mathrm{Eu}(\mathrm{NO_3})_3 L_2] + L' \Longrightarrow [\mathrm{Eu}(\mathrm{NO_3})_5 LL'] + L$$

The reaction rate is independent of the concentration of added ligand and this is in accord with a dissociative mechanism

$$[\mathrm{Eu}(\mathrm{NO_3})_3 L_2] \xrightarrow{k_1} [\mathrm{Eu}(\mathrm{NO_3})_3 L] + L \tag{1}$$

$$[\mathrm{Eu(NO_3)_3}L] + L' \xrightarrow{k_2} [\mathrm{Eu(NO_3)_3}LL']$$
 (2)

The thermodynamic parameters of activation are as follows: $\Delta G^{\ddagger} = +15.0 \text{ kcal/mole}$; $\Delta H^{\ddagger} = +6.4 \text{ kcal/mole}$; $\Delta S^{\ddagger} = -28.9 \text{ cal/deg/mole}$ and $k_1 = 58 \text{ sec}^{-1}$ at 25°.

These data were obtained by a study of the 100 Mc/s ¹H nuclear magnetic resonance spectra of mixtures of the complex and ligand in deuterochloroform, in which measurements of the solvent vapour pressure showed no detectable association between complex and ligand. The complex [Eu(NO₃)₃L₂], where the Eu(III) ion is in rapid temperature-dependent equilibrium between the ⁷F₀ and ⁷F₁ states, gives the best resolved spectra of the complexes [$M(NO_3)_3L_2$], where M is a paramagnetic lanthanide. The aromatic and α -CH₂ proton resonances of the europium

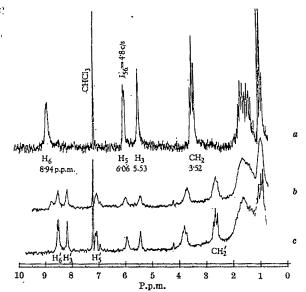

Fig. 1. 100 Mc/s 'H nuclear magnetic resonance spectra in deutero-chloroform: (a) $[\mathrm{Eu}(\mathrm{NO}_3)_2 L_2]$ at 50° C; (b) $[\mathrm{Eu}(\mathrm{NO}_3)_2 L_3]$ (28-0 g/l.) and $L(23\cdot1$ g/l.) at 20° C; and (c) mixture as in (b) but at 0° C. Unprimed peaks are those of the complex, primed peaks are those of the ligand. Assignments are by comparison with coupling constants of 2,2'-bipyridyl' and by comparison with $[\mathrm{Eu}(\mathrm{NO}_3)_2(5,5'-\mathrm{din-butyl-2},2'-\mathrm{bipyridyl})_2]$. δ -values are relative to an internal TMS standard.

complex show substantial shifts from the mutually rather similar values for the free ligand and the diamagnetic lanthanum, yttrium and lutetium complexes. On the addition of free ligand, the resonances are broadened (Fig. 1) but the spectra of the free ligand and of the complex remain distinct. The line width of the spectrum of the complex is constant at 0° C between complex to ligand molar ratios of 1:0.2 and 1:1.5, and the rate-determining process is thus independent of the added ligand. A typical plot of the line width parameter, in this case that of the 3-proton, against temperature (Fig. 2), shows the onset of exchange broadening at about 250° K and its subsequent dominance over the normal decrease in line width with increased temperature observed for a paramagnetic complex alone. The values already quoted for ΔH^{\ddagger} and ΔS^{\ddagger} were obtained by use of the relationship²

$$1/T_2 = 1/T_{2M} + 1/\tau_M$$

where T_2 is the observed transverse relaxation time, given by $1/T_2 = \pi w$ (w being the line width at half height in c/s), and T_{2M} is the transverse relaxation time in the absence of exchange (determined by the low temperature part of Fig. 2). τ_M is the average co-ordinated lifetime of any ligand molecule.

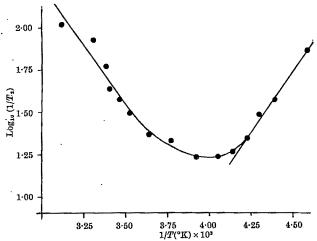

Fig. 2. Plot of temperature variation of line-width parameter for 3-proton of $[Eu(NO_3)_3L_2]$ for the solution corresponding with the spectra in Figs. 1(b) and (c).

The kinetics of reactions of lanthanide complexes have been little studied previously, but those studies which have been performed $^{3-5}$ when considered together with the general chemical properties of these compounds suggest that they are very labile. Thus dissociation in water of the mono-murexide complex of lanthanum into ligand and hydrated lanthanum ion has been shown by the temperature-jump method to have $k=3\cdot 2\times 10^4$ sec⁻¹ at 12° C while the reverse reaction has $k=8\cdot 6\times 10^7$ sec⁻¹.

Two further points are noteworthy. First, the contrast between the second-order kinetics of the exchange between $[MX_2(\mathrm{PPh_3})_2]$ and $\mathrm{PPh_3}$ $(M=\mathrm{Co,\ Ni;\ }X=\mathrm{Br,\ }I)$ in chloroform and our presently described first order reaction is in accordance with the simple proposition that the nickel or cobalt ion, being only 4 co-ordinated, might be susceptible to nucleophilic attack while the europium ion, which here is perhaps 10-co-ordinated, would be too well shielded for this mechanism to operate. Second, the small value of ΔH^{\ddagger} suggests that the transition state may be stabilized by co-ordination of the dipolar chloroform molecules with the europium ion.

One of us (J. E. N.) was supported by a grant from the Science Research Council.

MOLECULAR STRUCTURE

Two Structurally Distinct Classes of Kappa-chains in Human Immunoglobulins

The general structural features of the various types of immunoglobulins are known and the details of the primary structure are gradually being filled in. A characteristic feature of the immune response, however, is its specificity and here the data have not been sufficient to reveal the structural basis of the specificity and even less the underlying genetic mechanism. The aim of the present investigation was to throw more light on this problem, and to this end we have determined the NH₂-terminal sequences of a large number of x-chains and made a comparison of their structures.

The sources of the x-chains were 18S macroglobulins, myeloma proteins and Bence-Jones proteins, all of immunological type K, obtained from patients suffering from macroglobulinaemia and myelomatosis, respectively. The serum proteins were isolated according to the procedures of Gelotte et al. and Fahey and Horbett². The purified IgM, IgG and IgA were partially reduced with mercaptoethanol, alkylated with iodoacetic acid and the light and heavy chains separated on 'Sephadex G-100' according to the procedure of Fleischman et al.³. The light chains of pooled human γG were prepared from the Cohn fraction II-1,2. The preparation was enriched in x-chain content by the procedure of Cohen and Gordon⁴. The urinary proteins were purified as described by Fahey and McLaughlin⁵.

The two mouse (M) sequences are taken from the work of Gray et al., and the human (H) sequences are all from the present work. Amino-acid symbols in bold face indicate major components in the pooled light chains of IgG.

Samples (approximately 7 mg) of the x-chain preparations were subjected to twenty-two degradation cycles in the protein sequenator using the technique already described. The results of these degradations are shown in Table 1, which also includes the NH2-terminal sequence of two mouse Bence-Jones proteins' for comparison.

A comparison between the structures reveals several The sequences consist of variant and nonvariant sections. The essentially non-variant positions are Nos. 2, 5-8, 11-12, 14, 16, 18 and 20. Exceptions do occur—for example, position 2 in Gra(H), position 12 in 70(M), position 16 in Cra(H), and position 20 in 41(M). In the variant positions the choice is usually between two amino-acids, for example, aspartic or glutamic acid in position 1, valine or glutamine in position 3, and leucine or methionine in position 4. Occasionally a third and even a fourth amino-acid is observed, though less frequently, for example, in position 13. The sequences are 'in phase", that is, without deletions or insertions. The amino-acids occupying the variable positions in the human x-chains vary in conjunction over the whole sequence. It is therefore possible to divide the human \varkappa -chains into two structurally distinct classes. If $\mathrm{Tra}(H)$ is chosen as the prototype of one class, it is found that Cra(H), Pap(H), Lux(H), Mon(H) and Con(H) will differ from the prototype in only six out of fifty-five variable positions. With Smi(H) as the prototype for the other class comprising Nig(H), Win(H), Gra(H) and Cas(H) also, the corresponding figures are seven out of forty-four. These observations seem to justify the division of the x-chains into two classes and we propose the provisional terms x_{Tra} and x_{Smi}. A division of the x-chains according to structure has in fact been surmised by Putnam et al.8 on the basis of limited sequence data.

The earlier non-recognition of the two classes of x-chains has probably led to an overestimation of the variability in the NH2-terminal half of the structure. The average number of amino-acid replacements in our material is 1.3 for each twenty-two positions. If this frequency is representative of the NH2-terminal half of the x-chains, it would mean an average of six to seven replacements in the variable part of an individual x-chain.

The amino-acid replacements observed, both in the variant and in the essentially non-variant positions, occur only singly. There are no replacements of stretches of amino-acid as one would expect if a genetic crossing-over mechanism were responsible for the replacements. Within the classes all replacements are in fact consistent with a single base mutation in the codon. On the other hand, a comparison between the two prototypes shows that in three positions, that is numbers 3, 13 and 15, two-base mutations are required for the replacements.

A comparison between the NH2-terminal sequences of two Bence-Jones proteins, Cra(H) and 41(M) originating one from man and the other from mouse, shows identity

in the first fifteen amino-acids. An extensive similarity of this kind could not be fortuitous. The simplest explanation would be that the genetic information for the manufacture of this sequence stems from a germ line common to both species. The wider generalization that the entire sequence of the individual x-chain is predetermined by the genetic information carried in the germ line seems plausible.

The sequential degradation of the pooled x-chains shows, as would be expected, an extensive heterogeneity. When the individual sequence positions, however, are analysed for their amino-acid composition, they are found to resemble closely an average of the amino-acids occupying the corresponding positions in the individual z-chains. This lends further support to the assumption that the serum proteins associated with macroglobulinaemia and myelomatosis are true representatives of the normal immunoglobulins. This does not exclude the possibility that certain of the amino-acid replacements observed in the pathological proteins are expressions of the pathological condition rather than of the normal variability of the immunoglobulins themselves. This could, for example, apply to the more radical replacements from the point of view of protein conformation, for example, glutamic acid-lysine in position 1 of Nig(H), or glycine-arginine in position 16 of Cra(H). At the present stage, however, this is no more than conjecture.

We thank Mr M. N. Blake, Cancer Institute Board, Melbourne, for supplying the samples of purified Bence-Jones proteins and Mrs E. Minasian for technical assist-

Deuterium-Hydrogen Exchange of Collagen Like Synthetic Polypeptides

THE two models of collagen structure which have been developed since 1954 have been confirmed by X-ray diffraction studies of the collagen fibres. Both models are similar, the chief difference being in the number of

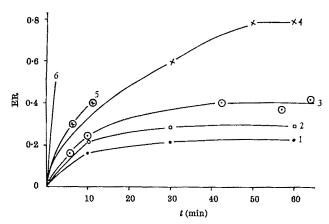

Fig. 1. The exchange rate (ER), which is a measure of the deuterium-hydrogen exchange, plotted against time. 1, Collagen; 2, poly-Dr-Ala; 3, poly-Pro-Ala-Gly, molecular weight, 2,500; 4, poly-Pro-Gly-Ala, molecular weight, 2,500; 5, poly-Gly-Ala-Pro, molecular weight, 2,100; 6, Pro-Ala-Gly-OMe.HCl.

hydrogen bonds. Rich and Crick¹ assumed that there was one hydrogen bond for each tripeptide unit (one bonded structure) while Ramachandran2 assumed two hydrogen bonds per unit (two bonded structure) in the structure he suggested. Thus differences in the sequence of the amino-acids and changes in the position of atoms are unavoidable. In the collagen structure II of Rich and Crick, position 1 of the tripeptide unit is always occupied by a glycine unit; the positions 2 and 3 may be occupied by any other amino-acid including proline and hydroxyproline. On the other hand, in the Ramachandran structure an imino-acid unit can only occupy position 3 if changes in the collagen structure are to be The results obtained by Harrington³ and Bensusan and Nielsen support the structure proposed by Ramachandran. Investigations into synthetic polypeptides composed of tripeptide units, such as gly-pro-hypro^{5,6} and pro-gly-pro⁷, have shown that only one hydrogen bond per tripeptide unit is sufficient for the formation of a collagen like structure in solution as well as in the solid state.

Until now, investigations into tripeptides containing three different amino-acids with an imino-acid in position 3, similar to the mentioned tripeptides, have not shown any tertiary structure. We have therefore synthesized a series of tripeptides corresponding to both the collagen structures proposed by Rich and Crick and the structure proposed by Ramachandran.

The synthesized tripeptides were polymerized using tetraethylpyrophosphites, and the resulting crude synthetic polypeptide polymers were recrystallized several times from alcohol/ether mixtures before being fractionated on 'Sephadex' columns. Fractions with similar molecular weights were then examined and the results compared. As the work on solutions is still in progress, we should like to report the results obtained with collagen films using the deuterium-hydrogen exchange technique. The exchange rate (ER) was measured by the method of Blout et al. using a Perkin-Elmer double beam spectro-photometer, model 221, equipped with a sodium chloride prism, and taking into consideration the increase in the amide II-band at 1,450 cm-1.

In Fig. 1, the quantity ER, as a measure of the deuterium-hydrogen exchange, is plotted against time. ER is derived from the following equation

$$\text{ER} = \left(\frac{A_2^{'}}{A_1}\right)_T - \left(\frac{A_2^{'}}{A_1}\right)_{T_0}$$

We have chosen the ratio of the optical density of the NDdeformation band (A'_{2}) to that of the amide I band (A_{1}) , for it does not change during deuteration. This ratio is independent of the concentration and the thickness of the sample. It is necessary to take the difference, because the intensity of the ND-deformation band is superposed by a CH-deformation band of constant intensity. Thus $(A'_2/A_1)_T$ is the ratio taken after a certain time and $(A'_2/A_1)_{T0}$ is the initial value before deuteration. Preparation of the samples for infrared investigations and the calculation of ER are described by Heidemann and Srinivasan¹⁰

Fig. 1 shows that the extent of exchange in the solid state in the sequence (gly-ala-pro), (5) and (pro-gly-ala), (4) is higher than in $(gly-pro-ala)_n$ (3), and therefore the structure of $(gly-pro-ala)_n$ is more stable than the other For comparison, the exchange rates (ER) sequences. of acid soluble collagen, poly-DL-alanine and L-prolyl-L-alanylglycin-methylester-hydrochloride are also included. All substances are soluble in water and this eliminates any hindrance of the exchange by hydrophobic effects.

The polypeptides containing the sequence (gly-ala-pro) (4 and 5), which corresponds to the Ramachandran twobonded collagen model, are seen to be less stable than polypeptides having the sequence (gly-pro-ala) (3), which are capable of forming a one-bonded structure as supposed by Rich and Crick. These findings also support earlier ones11.

The greater stability may also arise from the additive hydrogen bonds, which stabilize the quaternary structure favourably formed in the collagen model suggested by Rich and Crick.

These hydrogen bonds should also be considered in all cases where different investigations or measurements are carried out on collagen in the solid state.

IMMUNOLOGY

Balanced Synthesis of Light and Heavy Chains of Immunoglobulin G

WE have already investigated the production of immunoglobulin G (IgG) by mouse plasma cell tumour 5563 and have shown that light chains are released autonomously from polyribosomes into a pool of free light chains. The time course of incorporation of radioactive amino-acids into free light chain and the myeloma protein indicated that the pool of free light chains is small and reaches maximum radioactivity after about 10 min of incubation. It behaves as a pool with rapid turnover from which light chains appear to be incorporated into G myeloma protein molecules^{1,2}. These findings led us to propose the possibility that the pool of free light chains controls the release of heavy chains from the polyribosomes.

In view of the neoplastic nature of the 5563 plasma cells, we have now turned our attention to the synthesis and assembly of IgG in lymph nodes from hyperimmune mice. From the results reported here, we conclude that in normal conditions IgG secreting cells produce equal numbers of light and heavy chains with a small pool of light chains serving as an intermediate in the assembly of IgG molecules. No excess secretion of either chain could be detected. This does not exclude the possibility that a very small amount of light chain from the pool can reach the extracellular spaces produced by cell death, or unbalanced synthesis of occasional cells.

The experiment was as follows. Popliteal lymph nodes from mice immunized with haemocyanin were incubated for from 5 to 100 min with ³H-amino-acids. Intracellular IgG or any free sub-units released with deoxycholate were fractionated by sucrose gradient centrifugation and their radioactivity across the gradient was determined by precipitation with antisera specific for determinants on light chain or on heavy chain. The extracellular culture medium was also analysed for the presence of secreted IgG and its sub-units.

C3H/He mice received, in each hind footpad, 25 µg of alum precipitated haemocyanin (Maia squinado) mixed with 2.5×10^8 B. pertussis (Burroughs Wellcome vaccine) and after 6-10 weeks a further 10 µg of haemocyanin in saline. Six days later about one-third of the total protein synthesized in vitro by the draining popliteal lymph nodes was precipitable with specific antiserum to IgG.

Popliteal lymph nodes cut into 0.5-1 mm pieces were incubated for 5-10 min in Falcon dishes $(35 \times 10 \text{ mm})$ in 0.15 ml. of Eagle's medium buffered with tris, pH 7.4, containing 10 µc. each of ³H-L-leucine and L-serine and · 20 μc. of ³H-DL-valine. The pieces of tissue were washed twice with cold medium; soluble intracellular proteins released with 0.5 per cent deoxycholate were prepared by centrifugation on a density gradient (8 ml. of 30 per cent, 1 ml. of 10 per cent and 1 ml. of 4 per cent (w/v) sucrose) at 100,000g for 80 min. The top 2 ml. was concentrated and dialysed for 1.5 h against saline buffered at pH 7.4. Light chain and IgG were fractionated on sucrose gradients (4-20 per cent w/v) by centrifuging for 16 h at 35,000 r.p.m. in a Spinco SW 39 rotor¹.

To determine the radioactivity of IgG and light chains, samples of each sucrose gradient fraction were treated with: (a) excess antibody to light chain plus carrier light chain; (b) excess antibody to Fc-fragment plus carrier myeloma protein; and (c) goat anti-rabbit IgG and rabbit IgG (at equivalence). The antibody/antigen precipitates were washed twice with saline, suspended in 5 per cent trichloroacetic acid and counted on 'Oxoid' membranes as previously described^{1,3}. Antisera were obtained from rabbits hyperimmunized with papain fragment Fc or light chains separated from G myeloma protein 5563 G myeloma protein 5563 has x type light (Table 1). chains, which appear to be the prevalent light chains in the mouse. The antiserum to light chain precipitates 75-80 per cent of mouse IgG labelled with iodine-131 (prepared from mice immunized with haemocyanin4) and the antiserum to Fc 85 per cent (Table 1). In addition Dr D. Dresser and Miss H. Brown tested the ability of these antisera to develop IgG plaque forming cells (P.F.c.) in

Table 1. CHARACTERIZATION OF ANTISERA

	Absorbed		Reaction		Percentage of 131I-mouse IgG
	with	$oldsymbol{L}$	H	M.P.	precipitated
Anti-Fo Anti-L	Fab Fc	<u>-</u>	+ -	÷ ±	85 75–80
			A	(high b/Ag ra	atio)

Fo and Fab are papain fragments, L and H light and heavy chains, all prepared from G myeloma protein 5563 (M.P.)³. Mouse IgG was trace labelled with iodine-131 by the method of Hunter and Greenwood⁴ to a specific activity of 3 μ c./ μ g. Precipitation with antiserum was tested in the presence of carrier myeloma protein or light chains in the conditions used for antiserum treatment of sucrose gradient fraction.

spleen from mice immunized with sheep red blood cells. Both antisera developed about 90 per cent of the P.F.C. detected with their antiserum to mouse IgG⁶. This validates the use of these antisera for the present study.

The pattern of labelling light chains and IgG in intracellular protein released with deoxycholate is illustrated in Fig. 1. After incubating lymph node pieces for 5 min with 3H-leucine and 3H-valine, the radioactivity incorporated into light chains and IgG is of similar order. After 10 min there is a relative increase in radioactivity of IgG and after 40 min the intracellular IgG is more highly labelled than the free light chains (Fig. 1C). The antibody to light chain has a high antibody: antigen ratio and does not precipitate all of the myeloma protein in the presence of carrier light chain. Approximate ratios of radioactivity found in completed IgG versus the free light chain were calculated from the peaks of radioactivity specifically precipitable by antisera specific for Fc and light chain, respectively. The ratio changes from about

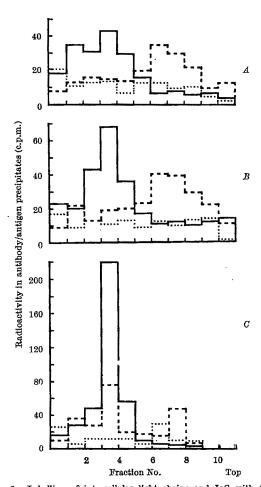

Fig. 1. Labelling of intracellular light chains and IgG with time. Lymph node pieces were incubated with ³H-L-valine, serine and leucine for (A) 5 min, (B) 10 min, and (C) 40 min. Intracellular proteins were fractionated on sucrose gradients (4-20 per cent w/v sucrose) for 16 h at 35,000 r.p.m. in a Spinco SW 39 rotor. Radioactivity of antibody/antigen precipitates in equivalent aliquots of the different gradient fractions using (——) antibody to Fc fragment, (———) antibody to light chain, and (.....) anti-rabbit IgG in the presence of rabbit IgC to serve as controls. The volumes loaded on to sucrose gradients were equal but represented varying proportions of the total soluble protein.

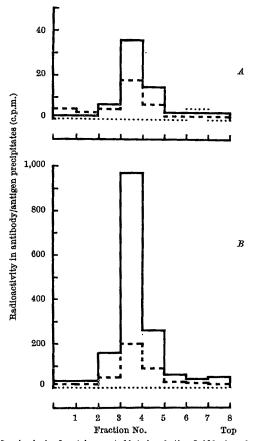

Fig. 2. Analysis of protein secreted into incubation fluid by lymph node. Sucrose gradient fractionation and treatment with antisera as in Fig. 1. Radioactivity in antibody/antigen precipitates using antiserum to Fc (——), antibody to light chain (———), and antibody to rabbit IgG (...). Extracellular fluid was collected after (A) 40 min and (B) 100 min of incubation at 37° with ³H-leucine and valine.

1 after 5 min to about 7 after 40 min of incubation (Table 2).

To ascertain that the change in the pattern of labelling of intracellular free light chain and IgG is not caused by more rapid secretion of light chain from the cell, compared with the myeloma protein, the incubation fluid was freed from cells by centrifugation for 10 min at 500g, and fractionated as described with added carrier G myeloma protein and light chain. Analysis of extracellular fluid obtained after 40 min of incubation of lymph node pieces (Fig. 2A) shows that only a little radioactive IgG and no radioactive light chain seem to be secreted from the cell during that time interval. After incubation for 100 min secreted myeloma protein is highly radioactive, but still no significant radioactivity was detectable in the light chain region with antiserum to light chain. It seems that the cells do not secrete significant amounts of light chain, and maintain the light chain pool within the cell.

Further evidence that we are dealing with a pool of free light chains which is rapidly turning over rather than with continuous excess synthesis of light chains comes from "pulse-chase" experiments. Two dishes with pieces of lymph node tissue were incubated for 10 min with ³H-leucine and ³H-valine. The incubation fluid was replaced with medium containing 0·1 molar non-radioactive L-leucine and L-valine for 5 min in the cold, and one dish was then incubated for a further 20 min at 37° C with fresh medium containing the high concentration of leucine and valine. The pattern of labelling of intracellular free light chains and IgG molecules released by deoxycholate was compared after 10 min of incubation with tritiated amino-acid (Fig. 3A) and, after the subsequent "chase", with non-radioactive amino-acids (Fig. 3B). The peak of radioactivity in free light chain is greatly reduced,

relative to that in IgG, during the chase incubation with non-radioactive amino-acids. The approximate ratio of radioactivity in IgG to light chain changed from 1.4 to 6 (Table 2). A higher proportion of the total soluble protein was loaded on to the gradient in Fig. 3B.

The present study using lymph node cells agrees well with our earlier findings with plasmacytoma 5563, which produces a G myeloma protein but no Bence-Jones protein. Like the 5563 tumour cells, lymph node cells present a pattern of balanced synthesis of light and heavy chains of IgG, but contain a small pool of free light chains rapidly turning over. The change in relative labelling of free light chains and IgG with time provides evidence for this turnover. After a short period of labelling (5 min), radioactivity is found to a similar extent in both free light chains and IgG. The relative labelling of light chains decreases with time so that after 40 min of incubation with radioactive amino-acids six or seven times as much radioactivity is found in IgG as in free light chain. The previous results with 5563 tumour cells were comparable except for a variation in the exact time relationships. An ascitic form of the plasma cell tumour 5563 was used which equilibrates much more rapidly with radioactive aminoacids than the small pieces of lymph node tissue incubated

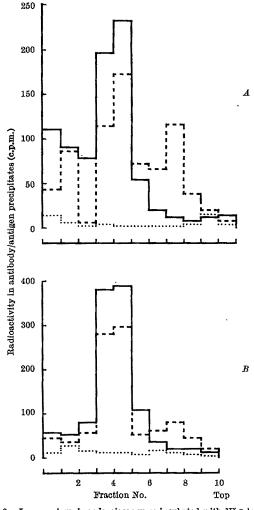

Fig. 3. Immune lymph node pieces were incubated with ³H-L-leucine and L-valine for (A) 10 min, and (B) 10 min and thereafter for 20 min with medium containing 0-1 molar L-leucine and 0-1 molar L-valine. The intracellular proteins, released with deoxycholate, were fractioned as in Fig. 1. Radioactivity in free light chain and IgG was determined by specific precipitation with (——) anti-Fc fragment, (———) antibody to light chain, and (...) anti-rabbit IgG. In this experiment a more hyperimmune anti-light chain serum was used which reacted more effectively with myeloma protein than with antiserum used for experiments illustrated in Figs. 1 and 2. (A) Two-thirds of the intracellular protein and (B) four-fifths were loaded on to the gradient, both in the same volume.

in this study, but the relative incorporation into light chains compared with IgG within each sample is highly

The pulse-chase experiment, in which the radioactivity in free light chains was greatly reduced relative to that in IgG after incubation with non-radioactive amino-acids adds weight to the idea that the pool of free light chains turns over as an intermediate in IgG assembly. We found no evidence for the secretion of excess free light chains into the extracellular fluid by the immune tissue.

Our results do not exclude the possibility that usually a very small amount of light chain may appear in extracellular fluids by cell death, shedding of the cytoplasm or unbalanced synthesis in occasional cells. In malignant plasma cells it is obvious that imbalance in synthesis of heavy and light chains occurs. In many plasmacytomas, in mouse and man, excess light chains are produced resulting in the appearance of Bence-Jones protein in the urine, or complete suppression of heavy chain synthesis or release occurs leading to Bence-Jones proteinuria with no detectable serum myeloma protein. În cells which continually synthesize excess light chains, the radioactivity of both light chains and myeloma protein increases with time7, whereas in the 5563 tumour the labelling of free light chains reaches a maximum after about 10 min of incubation2.

Our findings that in mouse lymph node cells there is no detectable excess synthesis of light chains accumulating in or being secreted by the cells contrast with the findings of Shapiro et al.8, using rabbit lymph nodes. ported that cell suspensions of lymph nodes from hyperimmunized rabbits synthesize and secrete into the culture medium an excess of free light chains when tested after I h of incubation. Labelled IgG and free light chains were identified in the intracellular and extracellular fractions, before and after reduction with mercaptoethanol in urea and sodium dodecylsulphate (SDS) by their position on acrylamide gel electrophoresis in the presence of SDS. This method separates molecules chiefly by size, and so the background of labelled proteins of similar size to light chain and reduction of other labelled proteins to sub-units of that size make the quantitation of radioactivity in light chain problematical.

Nezlin and Kulpina, purified in vitro labelled rabbit intracellular and extracellular immunoglobulins by absorption on a specific immune precipitate. On fractionation using 'Sephadex G-200' a "microglobulin" (smaller than ovalbumin) which is probably free light chain was found to contain only 5 per cent of the radioactivity of the immunoglobulins; this is consistent with our present results but would not agree with a large overproduction of light chains.

We conclude that in lymph nodes from immune mice there is an overall balanced synthesis of light and heavy chains of IgG. The lymph nodes contain also a small pool of free light chains which appears to turn over rapidly and to serve as an intermediate in IgG assembly. We could not detect secretion of free light chains from the cells.

We thank Mr Brian Wright for his help.

Effect of Neonatal Thymectomy on **Experimentally Produced** Immunological Cardiac Lesions

IMMUNOLOGICAL cardiac injury can be produced in experimental animals by the administration of: (a) homologous or heterologous heart extract with Freund's adjuvant; (b) passive transfer of humoral anticardiac antibodies; or (c) after passive transfer of cellular antibodies either through intravenous injections of immune cell suspension or by transplantation of immune spleens1.

Animals thymectomized at or shortly after birth are less able than unthymectomized animals to develop a normal immune response. This is demonstrated by an impaired ability to reject homograft and heterografts and lowering of the concentrations of circulating antibody to various antigens, both soluble and particulate 2-4. Immunological cardiac injury is caused both by circulating antibody and delayed hypersensitivity mechanisms, and so we decided to see whether it could be influenced

by neonatal thymectomy.

Albino rats 1-3 days old were thymectomized in the following way. Animals were placed in a glass container and chilled in a refrigerator at 4° C. Within 20 min deep hypothermic anaesthesia had been reached. The animal was pinned on a cork board and, in aseptic conditions, the chest was opened after a midline skin incision had been made. The thymus was freed from all attachments by blunt dissection and removed, usually intact. The wound was closed by interrupted sutures and the animal was warmed to room temperature. Control animals were treated similarly but without removing the thymus.

The animals were weaned when 3-4 weeks old and were fed on a balanced diet. They were sensitized at 15-16 weeks—the interval allowed for elimination of any preformed lymphocytes. Thymectomized and control animals were given six weekly subcutaneous injections of 10 per cent saline extract of mouse heart in 0.25 ml. doses mixed with an equal volume of Freund's adjuvant. The animals were killed I week after the last injection, and blood was collected for antibody estimation. The heart was removed carefully and preserved in 10 per cent formalin for histological study. Spleens of thymcctomized and control animals were removed and transplanted immediately into the omenta of normal adult rats. The spleen from one of the rats was transplanted into two animals. This technique was used to demonstrate cellular antibodies because of difficulty in demonstrating delayed hypersensitivity on the skin of sensitized rats. Recipient animals were killed 24 and 48 h after transplantation of the spleen, and the heart was examined for histological evidence of injury caused by cellular antibodies. Circulat ing antibodies were demonstrated by the tanned red cell

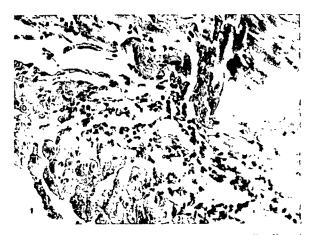

Fig. 1. Heart of rat given mice heart extract and Freund's adjuvant, showing damaged muscle fibres infiltrated by mononuclear and mesenchymal cells. (Stained with haematoxylin and cosin. × 150.)

agglutination (TRCA) technique in the sera of both groups of animals. All these methods have been reported in detail elsewhere. Only those animals which had no residual thymus were counted in the results.

Hearts of non-thymectomized control animals showed focal granulomatous cardiac lesions characterized by myofibral necrosis, mononuclear cell aggregates and mesenchymal reaction (Fig. 1). Circulating anticardiac anti-bodies in the sera as determined by the TRCA technique were found in varying titres in different animals; the highest was 2,560, the lowest 160 and the mean 720. The histological appearance of the hearts of recipients of spleen transplants was similar to those of control animals but the injury was more moderate in degree. The thymectomized animals, however, showed no cardiac damage after sensitization. The circulating antibody titre was considerably less than 10, and the cellular antibody could not be demonstrated by spleen transplantation in normal animals; the hearts of recipients of spleen transplants showed no evidence of injury (Table 1). Animals given normal spleen transplants showed no cardiac injury.

Table 1. EFFECT OF SPLEEN TRANSPLANTATION

Group	Circulating antibody titre (mean)	Pathological changes in heart	Pathological changes in the heart of recipient of spleen
Thymectomized	<10	0	0
Control	> 720	+++	++

Our results demonstrate that cellular as well as circulating antibodies produce cardiac damage in sensitized animals. In immunologically disturbed animals (thymectomized), cardiac antigens cannot provoke an immunological response and therefore no cardiac damage occurs. Our results also confirm the findings of Jankovic et al.5 that in neonatally thymectomized rats the production of circulating antibody and delayed hypersensitivity is depressed. Our results also agree with reports that allergic encephalomyelitis cannot be produced in neonatally thymectomized animals.

We thank K. G. Srivastava for technical assistance.

Phylogenetic Differences among the **Gm Factors of Non-human Primates**

THE Gm factors are a group of genetically determined antigens located on the heavy chains of γG globulin¹. Their presence in non-human primates¹⁻⁷ has permitted a comparative immunological study giving information about the antiquity of the various Gm characters.

Sera of eleven different species of non-human primates were surveyed using seven Gm typing systems of established specificities^{8,9}. The factors tested for included $Gm(x)^{10}$, $Gm(y)^9$ and $Gm(g)^{11}$ not previously reported in primates, as well as Gm(a), (f), (b) and (x)*. The species were grouped according to the degree of similarity between their Gm antigens and those found in man (Table 1)

Table 1. COMPARISON OF GM ANTIGENS OF MAN AND NON-HUMAN PRIMATES

Family	Species	No. tested	γ((z)	l he	m fa eavy (f)	chai	n* y(33 (g)
Hominidae	Man Gorilla Chimpanzee	$\frac{2}{12}$	6 7 6	6 6 6	<u>8</u>	<u>5</u>	7 6 7	<u>5</u>
Pongidae (Great apes)	Gibbon† Orang-utan Baboon Drill Rheaus monkey Cynomolgous monkey	12 15 33 1 16 5	6 6 4 4 —				7 8 8 8 8 8	
Cercopithecoidea (Old World monkeys)	Black ape Patas monkey Vervet monkey	2 23 10	=	=	NT _		8 —	=

The reagents used for testing are given in ref. 9. All samples of each species studied gave the same result. The anti-Gm(h) system detected Gm (b3,4). The numbers used in this table which appear under the Gm factors refer to inhibitory units which are defined as the highest tube number of serial two-fold dilutions of a serum, initially diluted 1:20, which resulted in inhibition. The higher the number, the greater the inhibitory capacity of the Gm antigen. A difference of two units or more is considered significant. A line (—) indicates no Gm factor was found in a 1:20 dilution of the primate serum. Gm(x) was also tested for and was not present in any species. NT, Not tested.

* The Gm antigens are grouped under the sub-class of heavy chain with which they are associated. **

† The twelve gibbons were Gm(a—) using one genetic agglutinator and Gm(a+) using a second Gm reagent. Nine of the gibbons were Gm(b+) and three were Gm(b—) using the same agglutinator.

using as criteria both the presence and the comparative inhibitory capacity of the Gm antigens.

The order established in Table 1 agrees with known ajor taxonomic divisions^{12,13}. The increase in the major taxonomic divisions12,13. number of Gm antigens and in their inhibitory capacity parallels development within the primate order. Highest in the ranking were the gorilla and chimpanzee (Gm(z+, a+, b+)), an associated sequence of factors found in many humans. The presence of this human-like group of genetic characters at high inhibitory levels suggests that these two apes are phylogenetically close to man. Similar relationships among primates have been constructed from studies of the antigenic correspondence of serum albumin¹³ and comparative investigations of the amino-acid sequences of haemoglobin in animals¹⁴. Moor-Jankowski and Wiener15,16 tested the Rh-Hr reactions of primate red cells and concluded that the chimpanzee red cell antigens were closest to man, followed by the gibbon, gorilla and orang-utan, while a study by Masouredis et al. using isotopic measurements of the uptake of iodine-125 anti-RhO(D) by simian red cells placed the orang-utan nearer to man than any of the African apes17.

The taxonomic level at which each Gm character is first detected provides a clue to the antigens' antiquity. Gm(y), (g) and (x) appear to be the most recent while Gm(b) followed by Gm(z) and (a) are the more ancient (Table 1). Gm(f) occurs in several Old World monkeys at a small fraction of the inhibitory level seen in man, and this finding probably represents a weak cross reaction. If this reasoning is valid, then the primary structures responsible for the Gm antigens were established at quite different times during the development of the primates. The presence of each Gm antigen would be expected to be dependent on the previous development of the subclass of YG heavy chain 18,18 on which the factor is localized, and so the Gm antigens associated with the \(\gamma G1 \) and \(\gamma G3 \) sub-classes of heavy chains are considered separately. (The nomenclature used for the heavy chain sub-groups of YG globulin is that adopted by a sub-committee of WHO: γG1 (We or γ2b); γG2 (Ne or γ2a); γG3 (VI or γ2c); γG4 (Ge or γ2d).) Particularly striking is the complete absence of Gm(g)¹¹ despite the relatively long established presence of the allelic Gm(b) factors, suggesting that the former factor may be a recent mutation. During this study Gm polymorphism was detected only for Gm(b) in gibbons. Although polymorphism among non-human primates has been described for other Gm and Inv antigens^{1,3,6}, it is very limited when compared

^{*} WHO notations for the genetic factors are as follows: Gm(a) is Gm(1); $Gm(b^{a,4})$ are Gm(13,14); Gm(x) is Gm(2); Gm(f) is Gm(4); Gm(g) is Gm(21); Gm(z) is Gm(17); Gm(y) is Gm(22).

with that of man, indicating that much of it arose in the higher primates.

The present study suggests that the Gm factors were still developing and changing in higher primates. Gm characters are believed to involve only a small area of γG heavy chains, and so this finding may not reflect the trend of changes in the whole immunoglobulin protein. Furthermore, no relationship between the Gm characters and antibody specificity or efficiency has yet been established which would indicate a selective evolutionary pressure. Notwithstanding these limitations, the comparative study of the Gm antigens has provided a useful technique to supplement other approaches to the study of immunoglobulin development.

I thank Dr J. Moor-Jankowski and the staff of the Facility for Forensic Serology, New York City, for primate sera, Dr J. Natvig for the Gm(g) reagents, Dr H. G. Kunkel for his help and advice, and Mrs F. Joslin for skilled technical assistance. This work was supported by a US Public Health Service special fellowship.

MICROBIOLOGY

In vitro Increase in Virus Infectivity

Some of the many previous reports of an in vitro increase in virus or of infectivity of plant viruses have been reviewed1,2, but the phenomenon is not generally accepted3. I believe that the work reported here with cucumber mosaic virus (CMV) in beet is simpler, gives a greater increase and will be more easily confirmed than previous reports. The results are interpreted as caused by slow inactivation of inhibitors of infection, not by an actual increase in virus.

To prepare inoculum, 0.05-0.1 g of systemically infected leaf tissue was ground in 1 ml. of water, usually containing 0.01 g potassium sulphate, diluted to 10 ml. with water; any further supplements were added and the preparation was mixed. This mixture was wiped over the primary leaves of cowpea (Vigna sinensis (Torner) Savi variety Blackeye) immediately after grinding and up to 10 h later. This latter we called aged inoculum. 'Celite', added last to the inoculum, served as an abrasive. Infections appeared as necrotic lesions in 1 day and were counted after 3 days. If more lesions appeared from aged than from fresh inoculum, it is believed that increase in infectivity occurred.

Principal positive results are shown in Table 1. CMV gave greater in vitro increase in infectivity than the viruses of tobacco mosaic, tobacco necrosis, tomato ringspot, tomato spotted wilt, artichoke latent or citrus tatter With CMV, greatest in vitro increase resulted with inoculum from beet. Moderate in vitro increase resulted with inoculum from cucumber and no in vitro increase resulted with inoculum from tobacco. Virus inhibitors in these hosts increase in the sequence tobacco-cucumberbeet4, and so there is a correlation of in vitro increase and concentration of inhibitors. With CMV from cucumber, consistent in vitro increase has resulted only with inoculum from the upper leaves of systemically infected plants, which inoculum has a low level of initial infectivity. No supplement has brought about a clear in vitro increase in infectivity with inoculum from cucumber.

CMV from sugar beet, especially from young inner leaves of plants which have been systemically infected for 2 months or more, has a low level of infectivity in the absence of supplements. Bentonite greatly increased initial infectivity but did not bring about an increase in infectivity with time. Potassium sulphate is the only chemical tested which when used alone (but in the presence of abrasive) brought about a large increase in infectivity with time. When charcoal (C, Merck's activated charcoal has been superior to five other brands) was added after dilution the in vitro increase was much greater than with potassium sulphate and 'Celite' only (Table 1). C may function as an abrasive and as an inactivator of inhibitors, but in this situation with the abrasive 'Celite' present, the inactivation of inhibitors by C is considered dominant.

The greatest in vitro increase in infectivity in CMV from sugar beet yet observed has been with potassium sulphate added before grinding, and potassium phosphate, C and 'Celite', in this order, added after dilution. In the last seven trials, the infectivity of this inoculum (after ageing for 4 h at about 25° C) has averaged 548 times and reached a maximum of 1,800 times that of the fresh inoculum. Many variations of this inoculum, such as higher and lower potassium sulphate, potassium phosphate and C, have brought about similar but lower increases in infectivity. Potassium phosphate increased initial infectivity, but caused a rapid loss of infectivity with time except when used with both potassium sulphate and C.

In vitro increase in infectivity could be caused by an actual increase in virus, by cyclic changes in the susceptibility of the host or by inactivation of inhibitors. Increase in virus seems unlikely because even the highest infectivity of aged inoculum has been lower than the initial infectivity of the same concentration of virus with bentonite, because the rate of increase in infectivity has

Table 1. In vitro increase in infectivity of cmy

been greater than any known for the increase of any plant virus, and because transfer of the aged inoculum to fresh substrate has not brought about any further increase in infectivity. Diurnal cyclic changes in the susceptibility of the indicator host seem an unlikely explanation because the phenomenon has been expressed at all times of the day. Decrease in activity of inhibitors is considered the correct interpretation.

Influence of Host Age on Leukaemogenesis and Virus Proliferation after Infection with a Murine Leukaemia Virus

WITH few exceptions, the virus induced thymic lymphomas in mice are strongly dependent on age1-4. Early passages of virus were leukaemogenic only for mice less than 2 days old. After repeated passage of the virus, however, the age specificity diminished and leukaemia could be induced in older mice. Even in these systems, host susceptibility still decreases with advancing age as measured by the increasing latent period between virus inoculation and the development of leukaemia. Despite repeated reports of optimum susceptibility in young animals, there is at present little information available about the cause or mechanism of this phenomenon. The elucidation of its mechanism has been complicated by the fact that both susceptibility to virus infections (for example, ref. 5) and susceptibility to tumour cell transplantation 6-8 have been shown to be enhanced in younger animals. The virus induced thymic lymphomas are convenient for resolving this problem, for the development of viraemia in these systems is separated by some 40-70 days from the first appearance of tumour cells⁹⁻¹³. It was possible therefore, with this system, to determine the influence of host age on virus proliferation independently of the development of leukaemia.

A 20 per cent extract in physiological saline (w/v) of thymuses, spleen and lymph nodes was prepared from mice infected with a murine leukaemia virus (Rich), as Virus preparations were used immediately or stored at -70° C in sealed glass ampoules. Virus was diluted in physiological saline and injected intraperitoneally, in amounts proportional to body weight. Newborn (1-3 day), suckling (4-6 day) and adult mice received 0.1, 0.5 and 1.5 ml., respectively, of a 2×10^{-1} dilution of stock virus.

To determine the titre of infectious virus, organs were suspended in saline and a 20 per cent (w/v) extract prepared by gentle homogenization in a chilled Potter-Elvehjem homogenizer. Cell-free preparations were prepared as previously described¹⁴. Groups of newborn (about 2 day) mice were inoculated intraperitoneally Groups of newborn with 0·1 ml. of the appropriate dilution of extract. Animals were examined at regular intervals for lymph node, spleen and mediastinal enlargement. Diagnosis of lymphoma was confirmed by gross and microscopic pathology using criteria previously described15. Median latent period as

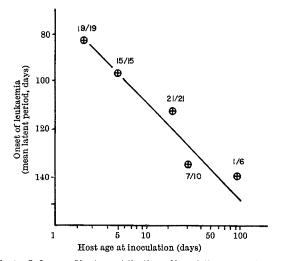

Fig. 1. Influence of host age at the time of inoculation on the development of virus induced leukaemia. Latent period represents the time interval between virus inoculation and the appearance of palpable tumour. Latency is inversely proportional to susceptibility. Numbers above each point represent the incidence of leukaemia (number leukaemic/number inoculated).

indicated in Table 1 represents the time interval between inoculation and the day when 50 per cent of the group inoculated are leukaemic. It is inversely proportional to the potency of the preparation being assayed 16-18.

To determine the influence of age on the susceptibility to virus induced leukaemia, we inoculated groups of random bred ICR/Ha Swiss mice ranging in age from 2 to 90 days with a dose of virus proportional to their body weight. It can be seen from Fig. 1, using the mean latent period for each group as a measure of relative susceptibility, that leukaemia development was strongly age dependent in this system. A latent period of 138 days (incidence: 1/6) for mice inoculated at 90 days old can be contrasted with a mean latent period of 83 days (incidence: 19/19) for animals inoculated at 2 days old14. Groups of mice at intermediate ages exhibited a latent period proportional to the age at which they were inoculated.

Table 1. EFFECT OF HOST AGE ON VIRUS PROLIFERATION AFTER INOCULATION OF A MURINE LEUKAEMIA VIRUS (RICH)

Age of host at inocula- tion	Organ assayed	Dilution (2×10*)	Virus assay No. leukaemic No. inoculated (%)		Median latent period (days)*
2 days	Thymus	-2	6/6	(100)	96
	****	-4	2/6	(33)	
70 days	Thymus	-2	8/8	(100)	79
		-4	4/5	(80)	113
2 days	Liver	-2	6/8	(75)	142
		-4	0/8	(0)	
70 days	Liver	-2	4/5 2/7	(80)	135
		_ 4	917	(98)	

*Time elapsed between inoculation and the appearance of palpable tumour in 50 per cent of the animals inoculated.

The thymuses and livers of mice inoculated at 2 day and 70 day old were assayed for virus content by inoculation of organ extracts into newborn mice.

To determine whether the diminished leukaemic response of older mice was caused by decreased competence to synthesize infectious virus, the following experiment was carried out. Groups of ten mice 2 and 70 days old were inoculated with a dose of virus proportional to their body weight. After intervals of 7 and 14 days the mice were killed. Thymuses and livers from each group were pooled, extracted and assayed for infectious virus.

The data for the groups assayed 7 days after virus inoculation are presented in Table 1. As shown by the incidence of leukaemia and latent period, the yield of infectious (leukaemogenic) virus from the thymuses of animals inoculated when 70 days old was somewhat greater than that obtained from mice inoculated when

2 days old. Similarly, with liver, a shorter latent period indicated higher virus yields from animals inoculated at 70 days. When liver extracts were diluted to 2×10^{-4} , activity was detected in the 70 day but not the 2 day age group. The results obtained with both age groups assayed 14 days after inoculation were essentially the same as those for 7 days and are not shown.

The increased viral titre observed in 70 day old as opposed to 2 day old mice probably resulted from the higher virus input dose employed19. Significant to this study, however, is the fact that the 70 day old mice, which were refractory to the development of leukaemia, were nevertheless completely competent to synthesize infectious

Thus the increased susceptibility of young mice to virus induced leukaemia is not a function of enhanced competence to synthesize infectious virus, but rather of some subsequent step in the leukaemogenic process. offers further support to the idea that viral proliferation and the subsequent steps in leukaemogenesis are separate although dependent processes3,26.

Cytopathic Effects of the Parainfluenza Virus SV₅ in Vero Cells

SIMIAN virus $5 (SV_5)$ (ref. 1), a member of the parainfluenzamumps-Newcastle disease subgroup of myxoviruses2, is a common contaminant of primary cultures of monkey kidney cells. SV5 virus multiplies to high titre in monkey kidney cells, but causes only minimal cytopathic effects3. Haemadsorption is necessary to show the presence of the virus⁴. In contrast, in BHK-21 cells, it produces extensive fusion and disintegration, yielding relatively little virus.

This communication describes studies on the multiplication of SV₅ virus in a continuous line of African green monkey kidney cells (Vero). Vero cells not only support the growth of SV_5 , but also produce marked cytopathic effects. These changes are produced equally well by virus previously adapted to other cell lines. SV_5 also produced plaques in Vero monolayers under agar overlay. Furthermore, complement-fixing and haemagglutinin antigen yields are high.

The virus used in this study was a laboratory strain and was passed twice in primary, African green monkey kidney cells and twice in continuous, embryonic rhesus monkey kidney ($MA \cdot 104$) cells (report in preparation). Vero cells were obtained from Dr Y. Yasumura, Chiba University, Japan, in 1964, and have been maintained in Medium 199 supplemented with 5 per cent foetal bovine serum, as previously described. The 117th to the 135th passage levels of Vero cells were used in this study. Cell cultures of primary rhesus monkey kidney, MA-104, and BHK-21, were obtained from Microbiological Associates, Inc., and were maintained in Eagle's minimum essential medium in Earle's balanced salt solution containing 3 per cent foetal bovine serum. Two to four tubes were used for each ten-fold serial dilution tested. cultures were observed for 21 days following inoculation. and the fluids were changed every 5 to 7 days. The 50 per cent endpoint was calculated by the Reed-Muench formula7. Plaque assays in Vero cells were carried out as Haemadsorption⁸ and haemagdescribed elsewhere⁶. glutination titrations with guinea-pig erythrocytes were carried out at 4° C and 37° C, respectively. Complement fixation tests were done in the microtitre system as described by Sever³. Titres were recorded as the reciprocal of the highest dilution showing 3+ or 4+ fixation of 1-8 units of guinea-pig complement.

For comparison, the virus was titrated simultaneously in Vero, $B\hat{H}K$ -21, and primary rhesus monkey kidney cell cultures. In Vero cultures inoculated with SV_5 virus in low virus dilutions, early cytopathic changes were evident within 3 to 5 days. Focal formation of dark, granular, irregular syncytia was the most prominent feature of these The highest dilution of the virus produced changes. detectable cytopathic changes by the ninth day after The cytopathic effects progressed to an inoculation. extensive degeneration of the entire cell sheet after an additional several days. Examination of infected cells on Giemsa stained preparations revealed intracytoplasmic inclusions surrounded by white haloes as reported

previously⁵.

Table 1. SV_5 virus titres in primary rhesus monkey kidney. BHK-21

Infectivity titre Vero TCD50Rh. Mk. 5·7† 6·7 BHK-21History AGMK/2; MA-104/2 AGMK/2; MA-104/2; Vero/1

• Infectivity titre expressed as $\log_{10}TCD_{bo}/ml$.

• Haemadsorption titre with guinea-pig erythrocytes at 4° C.

— Not done.

At the end of a titration, 21 days after inoculation, CPE-negative Vero tubes were tested for haemadsorption and always found negative. Cytopathic effects were also observed in BHK-21 cells, but the virus titres were lower than those obtained in Vero cells (Table 1). No cytopathic effects were observed in primary rhesus monkey kidney cells's, and assays were completed by haemadsorption. Table 1 summarizes the results. Titres obtained in Vero cells were similar to or higher than those obtained in primary rhesus monkey kidney cells.

Virus titrations in Vero cells were incubated simultaneously in stationary and rotating positions at 37° C. No significant difference in endpoints was observed, but the extent of the cytopathic changes was strikingly

enhanced in those incubated in roller drums.

 $SV_{\mathfrak s}$ virus plaques were obtained in Vero bottle cultures by using a double overlay procedure. Small irregularly shaped plaques were visible as early as the ninth day after inoculation. They increased in diameter to 1-0-2-0 mm by the twenty-first day. There was little or no increase in number after the twenty-first day. Repeated endpoint titrations of the same virus stock in Vero cells indicated that titres by plaque assay were at least half a log lower than those done by the tube culture method.

Neutralization tests were performed in Vero cell cultures with hyperimmune rabbit serum which was obtained from Microbiological Associates, Inc.

volumes of ten-fold serial dilutions of virus and diluted inactivated serum (1:20) were mixed. Serum-virus mixtures and control virus preparations were held at room temperature for 1 h before inoculation of 0.2 ml. amounts into each of four cultures. The development of either cytopathic effects or plaques by SV_5 was inhibited by type-specific immune rabbit serum.

Cell packs (20 imes), prepared from infected Vero cells on the fourteenth day after inoculation, reacted in complement fixation tests at dilution greater than 1:32 versus $SV_{\mathfrak{d}}$ antiserum. Moreover, tissue culture fluids of infected Vero cells gave an haemadsorption titre of 1:128.

Extensive cytopathic effect and plaque formation in Vero cell cultures make possible an efficient and reproducible direct technique for the demonstration of $\overline{SV_5}$ virus and of specific neutralizing antibodies. In addition, growth of the virus to high titre in a continuous simian cell line provides a convenient source of virus and its antigens for other studies.

This work was supported by the US National Institutes of Health, National Institute of Allergy and Infectious Diseases. We thank Mr H. C. Turner for performing complement fixation tests, and Tom Snyder, Sheila Rourke and Suzanne Gisin for assistance.

BIOCHEMISTRY

Determination of Switching-off and Switching-on Time of Overall Nuclear **RNA** Synthesis

There may be at least three modes of mRNA synthesis regulation in cultured mammalian cells: the repression of gene action as postulated in bacteria by Jacob and Monod¹; a mechanism in interphase nuclei $(G_1, S \text{ and } G_2)$ stages) involving mRNA synthesis only in the uncondensed chromatin and not in the condensed chromatin2,3; and the lack of or, at least, slowing down of mRNA synthesis in M stage cells. Inherent in the last mechanism is the tacit assumption that the overall mRNA synthesis is switched off about the beginning of M stage and on again about the end of the same stage4-13.

We have focused our attention on the third mode and have attempted to determine, by use of the life cycle analysis 14,15, the exact time in the life cycle when nuclear RNA synthesis is switched off and on. The mouse lymphoma cell line (L5178Y) (refs. 16 and 17) growing in suspension was used and, under our laboratory conditions, generation time was about 9-10 h. In these experiments, the uptake of uridine-5-3H into the nucleus of the cells, as seen in autoradiographs, was used to demonstrate nuclear RNA synthesis (possibly including mRNA synthesis). The silver grains in the autoradiographs of cells labelled with uridine-3H were removed on incubation with ribonuclease but not with deoxyribonuclease, indicating that most of the radioactivity was present as RNA labelled with uridine-3H.

To ascertain the switching-off time of nuclear RNA, two methods were used. The first was an application of

Time after the addition of ${}^3\text{H}\text{-compounds}$ (min)

Fig. 1. Estimation of the times of G_2 phase and of switching-off of over-all RNA synthesis by application of the method of Puck and Steffen (ref. 14). The horizontal distance between slopes of total mitotic cells (\blacksquare) and mitotic cells labelled with uridine- ${}^3\text{H}$ (\bigcirc) represents the time of switching-off of RNA synthesis (tsw). In this case, the time was 13 ± 2 min before mitosis. The horizontal distance between slopes of total mitotic cells and mitotic cells labelled with thymidine- ${}^3\text{H}$ (\times) represents the duration of the G_2 period (G_2). Functions of the accumulated mitotic index are: \blacksquare , $\log (1+m/n)$; \bigcirc , $\log ((1+m/n)/(1+m-m^*n))$; where n, total number of mitotic cells, m, total number of mitotic cells abelled with thymidine- ${}^3\text{H}$, and m^{**} , number of mitotic cells labelled with thymidine- ${}^3\text{H}$, and m^{**} , number of mitotic cells labelled with thymidine- ${}^3\text{H}$.

the method for determining the length of the G_2 period as described by Puck and Steffen¹⁴. To the exponentially growing cell populations, either colcemid (0.025 $\mu g/ml$.) and uridine-3H (1 µc./ml., 8 c./mmole) or colcemid and thymidine- 3 H (1 $\mu c./ml.$, 6 c./mmole) were added. Samples were removed from time to time and autoradiographs were prepared using Kodak NTB emulsion^{17,18}. Fig. 1 shows the results of one of two experiments. The exact time of switching off was calculated by using the equation derived previously14,18. In the two experiments, the switching-off time was 13 ± 2 min and 22 ± 11 min before mitosis. It is interesting that the time of switching off of DNA synthesis (at the end of the stage) occurred about 71 ± 12 min before the M stage.

In the second method for determining switching-off time, only uridine.3H was added to the exponentially growing cell population, and the ratio of the labelled mitotic cells to the total number of mitotic cells was estimated periodically. Fig. 2 shows one of three experiments. The switching-off time in the three experiments was found to be 9, 6 and 11 min. By summarizing the results of the two types of experiments, the average switching-off time can be placed at 12 ± 6 min before onset of the M stage.

The method for estimating switching-on time of nuclear RNA synthesis after mitosis required a synchronized cell population, which was achieved by the combined method of excess thymidine and colcemid previously described17. In the synchronized cell population, thymidine-3H was added during the last hour of the 5 h treatment with colcemid. Most S and G_2 stage cells were labelled by this procedure while most M stage cells were When the colcemid was washed out of the unlabelled. cell culture, uridine-3H (0.5 or 1.0 $\mu e./ml.$ and 8.0 e./ml.mmole) or thymidine-3H (0.5 or $1.0~\mu c./ml.$ and 6.0e./mmole) was added and samples were removed from time to time in order to estimate the percentage of labelled

Fig. 3 shows one of three experiments. Uridine-3H labelled cells appeared immediately after the anaphasetelophase counts reached a maximum, while thymidine-3H labelled cells appeared about 100 min after the appearance of uridine labelled cells. When thymidine-3H or uridine-3H was not added after colcemid treatment, the percentage

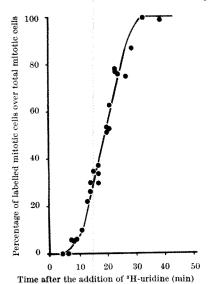

Fig. 2. Estimation of switching-off time of overall nuclear RNA synthesis by the rate of appearance of labelled mitotic cells. The switching-off time was estimated from the time $(t_{1/2})$ when 50 per cent of mitotic cells were labelled. The relationship of $t_{1/2}$ and the switching-off time is Switching-off time $= t_{1/2} + \frac{1}{4} \log \frac{1 + (m_0/2n_0)}{1 + (m_0/n_0)}$

where $a = \frac{\log 2}{\text{(generation time)}} = \frac{\log 2}{9.5 \text{ h}}$ and (m_0/n_0) is the fraction (0.035) of m stage cells in the exponentially growing cell population.

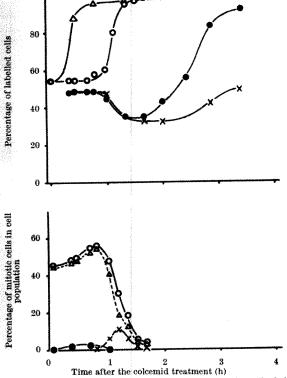

Fig. 3. Estimation of switching-on time of overall RNA synthesis by use of synchronized cell population. Upper figure: labelling of synchronized cells with thymidine. H(♠), with uridine. H(○), and with leucine. H(△). (×), Percentage of labelled cells in the synchronized cells after chasing with cold thymidine. Lower figure: percentage of mitotic cells in synchronized cell population. This represents the movement of unlabelled fraction of the synchronized population through mitosis. ○, Total mitotic cell; ♠, prophase cell; △, metaphase cell; ×, anaphase and telophase cells.

of labelled cells (crosses in Fig. 3) declined, indicating that the non-labelled portion of the synchronized cell population had divided, thereby decreasing the percentage of labelled cells. This decrease coincided in time with the increase of uridine-3H labelled cells. In other words, the cells started nuclear RNA synthesis around the end of mitosis. Close examination of dumbbell-shaped telophase cells revealed that the silver grains were present as soon as furrowing into two daughter cells occurred. This indicates that switching on time coincides with the end of

All previous observations of the switching off time of nuclear RNA synthesis in cultured mammalian cells were made on cells pulse-labelled with uridine-4H. It is interesting that the previous experiments implied two possibilities: the first that nuclear RNA synthesis does not occur in any stage of mitosis4-16; and the second that nuclear RNA synthesis occurs either in prophase only11,12 or throughout most of the mitotic cycle 15. In the latter case, the duration of pulse-labelling often lasted for 10 min or more 11,13 , enabling the G_2 cells to enter prophase; therefore such a result should be viewed with The present observations agree in principle caution. with the first and indicate that nuclear RNA synthesis does not occur during mitosis.

In conclusion, the overall nuclear RNA synthesis (uptake of uridine-3H into the acid-insoluble fraction of the nuclei), possibly into mRNA, was switched off completely about 70 min after the end of the S stage, or about 10 min before the M stage. The overall nuclear RNA synthesis began again at the end of cytokinesis of the Mstage, or approximately 100 min before the S stage of the next life cycle.

Finally, the interesting work of Johnson and Holland* and Buck et al. 19 suggests that M stage cells contain RNA polymerase and are able to synthesize RNA. If this is true, then mRNA synthesis must be switched off as a result of some mechanism, other than absence of enzyme. possibly a condensation of the chromosomes during the Mstage. Our present results are compatible with this idea.

In the present study, only the overall synthesis of nuclear RNA was determined and no information was obtained about whether mRNA for mitosis 20,23 was switched off at the same time as the overall RNA synthesis.

Appearance of Specific Acid Phosphatase Isozymes in the Synovial Fluid of Patients with Rheumatoid Arthritis

ENZYMES may occur in multiple molecular forms or isozymes¹, often showing tissue specific variations¹⁻³. In different pathological conditions² and after certain types of medication^{4,5}, alterations in serum isozyme patterns have been observed. These findings suggest that isozymes may be valuable markers in clinical research, for example, for the identification of the tissue origin of enzymes occurring in pathological levels in various body fluids. High levels of acid phosphatase activity have been reported in the synovial fluid⁶ and synovial tissue⁷ of patients with rheumatoid arthritis. This report deals with the appearance of certain acid phosphatase isozymes in the knee-joint synovial fluid of patients with rheumatoid arthritis.

Samples of synovial fluid were obtained by puncture of the knee-joint from thirty-six patients. Out of these thirty-six patients, twenty had the clinical diagnosis rheumatoid arthritis (in most cases confirmed by immunological reactions) and sixteen had other diagnoses such as arthrosis deformans, chronic unspecific synovitis, chondromatosis, osteochondritis and various chronic post-traumatic conditions. Samples of synovial membranes were collected from thirteen patients and serum samples were obtained from nineteen patients.

The synovial membranes were homogenized in a mechanical homogenizer in one volume of physiological saline and afterwards centrifuged. The supernatant fluids and the samples of synovial fluid and serum were examined by means of starch gel electrophoresis using a modification (2/3 dilution) of the discontinuous buffer system by Ashton and Braden*. After the electrophoresis the starch gels were preincubated for 30 min in 0·2 molar acetate buffer pH 4·0 and afterwards stained for 2 h in 0·2 molar acetate buffer pH 5·2 using α-naphthyl phosphate as substrate and fast garnet GBC salt as a dye coupler.

In the synovial fluid of seventeen out of the twenty patients with rheumatoid arthritis two distinct acid phosphatase components were found (see Fig. 1). None of the sixteen patients with diagnoses other than rheumatoid arthritis showed this pattern. Four different electrophoretically distinct acid phosphatase components, called A, B, C and D in order of decreasing anodal mobility, have been described in man. The components A and B occurred in the synovial fluid of patients with rheumatoid arthritis. In Fig. 1, a tissue extract of placenta is used to indicate the electrophoretic mobilities of the four components. The A and B components were not found in the sera of the nineteen patients of whom nine had rheumatoid arthritis. A weak acid phosphatase component, with a mobility slightly faster than that of acid phosphatase D, is sometimes found in serum and synovial fluid.

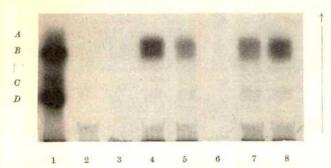

Fig. 1. Photograph of starch gel showing the electrophoretic acid phosphatase patterns in, 1, placental extract and 2–8, synovial fluids. Samples 4, 5, 7 and 8 are from patients with rheumatoid arthritis; 5 and 7 are repeated samples from the same patient. The arrow is indicating the direction of migration towards the anode.

In extracts of synovial membranes from thirteen patients there were variations in the acid phosphatase patterns. Six patients with rheumatoid arthritis (and a typical AB acid phosphatase pattern in the synovial fluid) had acid phosphatase components A, B and D in the synovial membrane. Out of seven patients without rheumatoid arthritis, five lacked acid phosphatase activity in the synovial membrane while two had weak acid phosphatases. Treatment with cortisone did not apparently affect the occurrence of acid phosphatase A and B in the synovial fluid. Three patients had an acid phosphatase component in their synovial fluid with a mobility faster than that of the A component. These patients had been given injections of cortisone into the knee-joint.

These preliminary results indicate that the occurrence of acid phosphatase components A and B in the synovial fluid is typical of rheumatoid arthritis. The acid phosphatase components are apparently derived from the pathological synovial membrane.

The high frequency of rheumatoid arthritis patients with the "acid phosphatase AB reaction" suggests that this synovial fluid alteration may be developed into a useful clinical test for rheumatoid arthritis.

Dissociation of Urease by Glycol and Glycerol

The existence of a urease of low molecular weight has previously been noted¹⁻³ but in circumstances that prevented ready characterization. We have shown that highly purified preparations of jack bean urease can be reversibly and rapidly dissociated without appreciable change in enzyme activity. The preparative molecular weight of 485,000 (ref. 4) is halved in the process.

Urease can be dissolved in 90 per cent propanediol or glycerol in concentrations up to 1 per cent protein. At pH 9-2 (1 part 0.02 molar tris EDTA buffer plus 9 parts diol or glycerol), urease dissociates completely in a few minutes. In the initial experiments, the electrophoresis pattern produced in acrylamide gel showed only one band, and because the mobility was substantially greater than that of the preparative form, the band observed was termed α-urease. Electrophoretic mobilities in gels of varying concentration and the sedimentation velocity in the ultracentrifuge were consistent with a molecular weight about half that of the original protein. It is possible to free the protein of the propanediol if the sample is dialysed against 0.02 molar tris EDTA, pH 9.2. Such solutions were used to determine the molecular weight by the meniscus depletion sedimentation equilibrium method⁵. At concentrations of 1 mg/ml. of protein, the molecular weight is 236,000, assuming $\bar{v}^4 = 0.733$.

When the pH of a solution of α -urease is reduced from 9·2 to 7·0, in the absence of propanediol or glycerol, there

BD

Fig. 1. Electrophoretic patterns of urease, acrylamide gel, 7 per cent; 0-02 molar tris EDTA buffer, pH 9-2. a, A, urease, 62 mg/ml. in 0-02 molar tris EDTA buffer at 20° C; B, solution in A diluted 1:10 with propanediol, after 1 h; C, solution in B after 2 h; D, solution in A after 2 h; E, solution in B diluted 1:1 with 0-68 molar phosphate buffer, pH 7-0, after 1 h. b, A, B, urease, same as column A in a; C, same as column B in a, but propanediol then removed by dialysing for 72 h against 0-02 molar tris EDTA buffer, pH 9-2; D, control for C, diol not removed.

is a rapid reassociation which can be easily demonstrated by gel electrophoresis. Fig. 1a, column E, shows the pattern obtained with a reassociated preparation. The mobility is slightly less than the native urease, although the sedimentation velocity indicated reformation of the 485,000 molecular weight species. Small amounts of higher oligomers are also evident. Even at pH 9.2 (Fig. 1b, column C) there is a slow reassociation in the absence of diol or glycerol. The amounts of reassociated material are, however, small enough to cause no interference with the determination of molecular weight by the methods used.

The activity of a-urease was easily shown by equilibrating the acrylamide gels in a solution of 1 g of Na2EDTA and 0.5 g of cresol red/l. of water and then placing in a similar solution containing 15 g of urea/l. Areas of urease activity are visible as purple bands on an orange background. The gel can also be stained for protein subsequently with amido black.

The specific activity of α-urease is nearly that of the undissociated form and has similar stability. Urease was assayed as previously described⁶ and protein was estimated by measuring the absorption⁶ at 278 mμ. A control solution of urease, 5.95 mg/ml., in 0.02 molar tris EDTA, pH 9.2, at 20° C had a specific activity of 217 at 0.5 h and 183 after 20 h. α-Urease in 90 per cent propanediol, 6.25 mg/ml., gave specific activities of 212 and 175. Because assays are made at pH 7, it seemed possible that z-urease reassociated during the assay conditions but assay at pH 9 yielded nearly identical values for undissociated urease and α-urease.

On the basis of gel electrophoresis patterns obtained from samples of urease dissolved in buffers of varying ionic strength and pH, and exposed to propanediol or glycerol, it is clear that low ionic strength and high pH predispose to complete dissociation. Careful electrophoresis of highly purified urease preparations (Fig. 1b, columns A and B) shows that, even in the absence of diol, traces of α-urease were present.

These experiments suggest that the common use of glycerol as a "preservative" for urease may be based on its effectiveness in dissociating the enzyme and inhibiting the precipitation of aggregates.

In vitro Hybridization of Normal and Variant Human Glucose-6-phosphate Dehydrogenase

NORMAL human glucose-6-phosphate dehydrogenase (Dglucose 6-phosphate: nicotinamide adenine dinucleotide phosphate oxidoreductase, EC 1.1.1.49) (G-6-PD) can be dissociated into smaller sub-units under certain conditions1-4, which suggests that normal and variant human G-6-PD may be hybridized in vitro. Studies of such hybridization may provide information on the polypeptide chains in which mutation occurred. Hybridization between human and rat G-6-PD has been observed, but despite the attempts made, no successful hybridization has so far been reported between the normal and variant human G-6-PD. We report here in vitro hybridization of the normal (B+), the common Negro variant with normal

red cell enzyme activity (A+) and the Seattle variant?.

G-6-PD was prepared from the blood of normal and variant individuals. The procedure used for the partial purification was the small scale modification of the method described previously4. Briefly, haemolysate (about 20 ml.) was placed on a 2×3 cm column of DEAE-cellulose buffered with 0.005 molar phosphate buffer pH 6.4 containing 10-3 molar mercaptoethanol, 10-3 molar EDTA and 10-5 molar NADP. The column was washed with about 10 ml. of the same buffer, and the G-6-PD which remained in the column was eluted with about 15 ml. of 0-1 molar phosphate buffer, pH 5-8, containing 0-5 molar sodium chloride. These procedures removed most of the haemoglobin and 6-phosphogluconate dehydrogenase from the haemolysate, and the recovery of G-6-PD activity was always better than 90 per cent. After adjusting the pH to 6.2 with 0.5 molar Na₂HPO₄ and adding disopropylfluorophosphate (10-4 molar) and NADP (5 × 10-5 molar), solid ammonium sulphate (35 g/100 ml.) was added to the eluent. After standing for several hours in the cold, the precipitates were collected by centrifugation. The enzyme could be stored in precipitated form for several months without significant loss of activity. Activities of the partially purified enzyme preparations were: 0.4-0.6 U/mg protein from B+ and A+ individuals and about 0.1-0.2 U/mg protein from the Seattle variant.

Dissociation and reactivation of G-6-PD were carried out in the following way. The enzyme precipitates (1-5 U) were dissolved in 2 ml. of 0.1 molar phosphate buffer (Na₂HPO₄-KH₂PO₄), pH 6·8, containing 10⁻² molar mercaptoethanol and 10-3 molar EDTA. An equal volume of diluted sulphuric acid containing 46 g of (NH4)2SO4/ 100 ml. was added to each enzyme solution. 0.2 molar H.SO, was used for B+ and A+ enzymes, while 0.1 molar H.SO, was used for Seattle G-6-PD. The samples were centrifuged for 10 min at 12,000g, the supernatants were discarded by capillary pipette, and the precipitates were resuspended in the same phosphate buffer. Precipitation

and resuspension were continued in the same manner until less than 20 per cent of the original activity remained. Four treatments when about 1 unit of enzyme was used or eight treatments when about 5 units of enzyme were used were usually required for the inactivation. All the treatments described were carried out at 0°-4° C. It has been shown that purified crystalline B+ enzyme dissociates into sub-units by this treatment, because after inactivation the molecular weight determined by the sedimentation equilibrium method was about one-half of the native active enzyme4.

One millilitre was taken from each sample for a reactivation control, and 1 ml. of each sample (containing approximately the same original activity) was taken to mix for hybridization. Each solution was adjusted to pH 6.8 by the addition of 0.5 molar Na₂HPO₄ and NADP was added to a final concentration of 10-4 molar. The solutions were incubated at 30°-35° C for 1 h and then kept at 4° C overnight. Siliconized tubes were used for both inactivation and reactivation.

The enzyme activity recovered was 60-100 per cent of the original activity. Attempts were made to inactivate and reactivate the enzyme (hybridization) by treatment with propanedithiol, which was used for hybridization of Drosophila 6-phosphogluconate dehydrogenase¹¹, by treatment with guanidine-HCl, which was used for hybridization of lactate dehydrogenases12, and by a modification of these methods. None of these procedures gave successful hybridization of human G-6-PD, but this does not exclude the possibility that suitable modification of these methods may hybridize human G-6-PD.

The mixture of inactivated B+ and A+ enzymes was reactivated as described and subjected to column chroma-Fig. 1A shows the elution diagram of the Compared with the diagram of the artificial sample. mixture of A+ and B+ enzymes, a new peak, indicating hybridization of the two enzymes, was recognized between the two original enzyme peaks.

The mobilities of A+ and B+ enzymes were not very different in starch gel electrophoresis, so the detection of

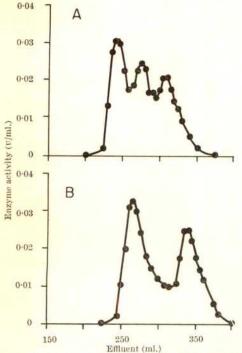

Fig. 1. Elution pattern of enzymes from a carboxymethyl-'Sephadex' column. The enzyme was placed on a carboxymethyl-'Sephadex' column (1-2×30 cm) buffered with 0-02 molar phosphate buffer, pH 5-7, and eluted with a linear gradient of sodium chloride with a concentration from 0-1 to 0-4 molar (mixing chamber 200 ml, each). Enzyme activity is expressed as the number of micromoles of NADP reduced per minute at 25°C. A. After hybridization treatment; B, mixture of A+ and B+ enzymes (without hybridization treatment).

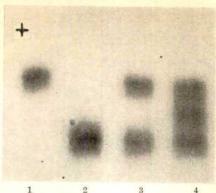

Fig. 2. Pattern of starch gel electrophoresis of G-6-PD. The conditions of electrophoresis (tris-boric acid. pH 8-5 (ref. 8)) and the development of the enzyme⁹ were slightly modified by addition of 10⁻⁹ molar NADP in the cathode buffer¹⁰. Starch was obtained from Electrostarch Co., Madison. 1, A+G-6-PD; 2, Seattle G-6-PD; 3, mixture of A+ and Seattle; 4, A+ and Seattle, after hybridization treatment.

hybrid enzymes, which should be located between A+ and B+, was not so easy as in the column chromato-

The hybridization between the Seattle variant and A+ enzyme could be demonstrated by starch gel electrophoresis (Fig. 2). Hybrid enzyme was detected between the two original enzymes used for the dissociation and co-reactivation. A similar result was obtained in the hybridization between the Seattle variant and B+ enzyme. It should be mentioned that each enzyme which was dissociated and reactivated separately showed identical electrophoretic mobility to the native enzyme.

These experiments revealed that dissociation and reactivation of any one type of G-6-PD gave only one enzyme which was apparently identical to the native enzyme, and that dissociation and co-reactivation of any two different types of G-6-PD produced one hybrid enzyme in addition to the two original enzymes.

The discovery that the hybrid G-6-PD is produced in vitro, and that, in contrast to autosomal 6-phosphogluconate dehydrogenase^{13,14}, no such hybrid enzyme has been detected in female heterozygotes, suggest that only one allele is functioning in any single cell of the heterozygous female. Since G-6-PD is sex-linked, this would imply the inactivation of one X chromosome in each female cell, as suggested by Lyon¹⁵.

Effect of BP8 Ascites (Sarcoma) Tumours on Glycolipid Composition in Kidneys of Mice

A NUMBER of neutral glycolipids which contain ceramide have been isolated from a variety of mammalian tissues including brain1, liver2,3, serum2, spleen2,4, erythrocyte2,3,5-7, kidney⁸⁻¹², lung¹³ and aseites tumours^{14,15}. The composition of glycolipids in strain-specific ascites tumours differed in different strains of mice 15, which suggested that the composition of tumour glycolipids could reflect the specificity of either the tumour or the mouse strain. Further studies showed that there were significant differences in the glycolipid compositions of the kidneys between certain strains of normal mice. We have now compared the glycolipids of the kidneys of C3H mice carrying a BP8ascites tumour with those of the kidneys of normal C3H mice and with those of the BP8 tumour and the results with reference to the tumour-carrying mice are of considerable interest and are the subject of this communication.

Structural analysis of the carbohydrate portions of the glycolipids by the permethylation procedure 16 , methanolysis and gas chromatography 17 of the methyl ethers showed that the glycolipids in the kidneys of normal C3H mice were glucosyl- $(1\rightarrow 1)$ -ceramide, galactosyl- $(1\rightarrow 4)$ -glucosyl- $(1\rightarrow 4)$ -glactosyl- $(1\rightarrow 4)$ -glucosyl- $(1\rightarrow 4)$ -ceramide, which was the principal component. Only traces of sulphatides were present.

Thin-layer chromatography¹⁸ of samples of the glycolipids isolated from the kidneys of C3H mice carrying BP8 ascites tumours (intraperitoneal injection) indicated a

composition similar to the normal kidney glycolipids; that is, a mixture of ceramide monohexoside, -dihexoside, -trihexoside and aminoglycolipid. The results from the structural analyses of these glycolipids, however, did not confirm this composition. The only methylated hexoside detected by gas chromatography after permethylation and methanolysis of the assumed ceramide trihexoside $fraction \ \ was \ \ methyl \hbox{$^{-2,4,6-tri-O-methyl}$ galactoside}.$ component, considered to be aminoglycolipid from its thin-layer chromatographic properties, gave only methyl-2,4,6-tri-O-methyl galactoside and methyl-2,3,6-tri-Omethyl glucoside in equal proportions—the two components were not ceramide trihexoside and aminoglytolipid. The methylated derivatives that were obtained from the glycolipids and their chromatographic properties on thin-layer plates of silica gel suggested that they were sulphatides. Each of the two compounds was treated with 0.05 normal methanolic hydrochloric acid for 2 h at room temperature¹⁸. The lipids were recovered from the reaction mixtures and examined by thin-layer chromatography on silica gel H with chloroform–methanol–water (65 : 25 : 4by volumes) as solvent. The two principal components now showed the chromatographic characteristics of a ceramide monohexoside and a ceramide dihexoside and not a ceramide trihexoside and aminoglycolipid, only traces of which remained. These results were in agreement with the known ready elimination of the sulphate group18 from ceramide galactoside-3-sulphate in mild acid conditions and supported the identification of the two glycolipids as ceramide galactoside-3-sulphate and ceramide glucosylgalactoside-3-sulphate. Confirmation of the presence of a sulphate group was obtained from their infrared spectra¹⁹. Both glycolipids (as potassium chloride disks) showed a strong absorption band at 1,240 cm⁻¹ characteristic of a

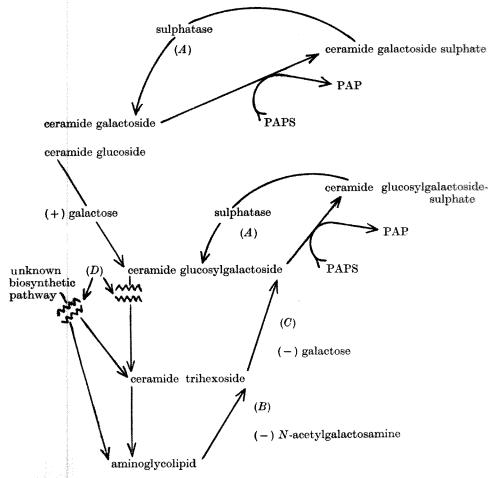

Fig. 1. Possible glycolipid interrelationships.

sugar sulphate. The intensity of the band shown by the ceramide monohexoside sulphate was much stronger than that shown by the ceramide dihexoside sulphate. Details of the glycolipid compositions of the kidneys from the C3H mice, with (a batch of 500) and without (a batch of 250) BP8 ascites tumours, and of the tumours, are summarized in Table 1. The fatty acid composition of the two sulphatides was typical of most mammalian glycolipids in containing a high proportion of lignocerie, nervonic and behenic acids. The distribution of these acids was similar to that in the sulphatides from human kidneys20,21.

The only apparent difference in the mice in the two batches studied was the presence of an ascites tumour, and in seeking an explanation for the considerable difference in their kidney glycolipids it seems reasonable to suggest that some product of the tumour cells is directly, or indirectly, capable of altering the metabolism and/or biosynthesis of one or more of the kidney glycolipids. This raises several interesting questions. Is the observed change in the glycclipids the result of the action of a single substance (for example, a tumour metabolite) produced by the tumour cells and released into the peritoneal fluid, from where it reaches the kidney through the systemic circulation, or the result of a number of biochemical and physiological disturbances arising from the presence and growth of the tumour cells in the host animal? Are the glycolipids in other tissues such as liver, spleen and lungs affected? Do other ascites tumours in other strains of mice produce similar effects? Other unpublished work of Dod and Gray has suggested that the glycolipids may occur exclusively in the plasma membranes of mammalian cells and therefore the question also arises of the possible effect of the change in glycolipid composition on membrane permeability and consequently on renal function.

The results from further comparative studies will provide answers to some of the questions, but it is difficult to relate the presence of the ascites tumour cells to some abnormality in the function of certain tissues of the host animal. A possible approach to the problem is through a study of the metabolism and biosynthesis of the glycolipids in the kidneys of the tumour-bearing animals. The biosynthesis of ceramide monohexoside sulphate probably involves the direct transfer of a sulphate group from 3'phosphoadenosine-5'-phosphosulphate²² (PAPS) to an acceptor substance (Fig. 1) which is ceramide galactoside23 or a ceramide galactoside-protein complex24. In the presence of a microsomal enzyme, galactocerebroside sulphokinase, esterification with the sulphate group occurs at the C-3 hydroxyl of galactose. The formation of ceramide lactosyl sulphate probably involves a similar mechanism. Ceramide glucoside is not a suitable substrate in this transfer system²³ and ceramide glucoside sulphate has not yet been detected in any mammalian tissue. A hydrolytic reaction causing a reversal of sulphatide synthesis has been demonstrated in normal brain and kidney tissue25, and Mehl and Jatzkewitz26 have shown that ceramide galactoside-3-sulphate is degraded by a lysosomelocated sulphatase in pig kidney. This particular sulphatase system contained at least two components, one of which is heat labile and appears to be identical with arylsulphatase type A. A deficiency or absence of this enzyme could allow an accumulation of sulphatide in the tissue and such a situation has been observed in the case of metachromatic leucodystrophy²⁶⁻²⁸. The increased concentration of sulphatides in the BP8/C3H mouse kidneys bears some similarity to the increased depositions of sulphatides in the kidneys in cases of metachromatic leucodystrophy. Martensson et al.²⁹, however, found that in this disease there was no significant change in concentration or relative distribution of the neutral glycolipids although the amounts of sulphatides were markedly increased, whereas in the BP8/C3H mouse kidneys the increase in sulphatides appears to be at the expense of two of the neutral glycolipids. It seems that the particular glycolipid composition

Table 1

found in the BP8/C3H mouse kidney might arise from a deficiency or inhibition of sulphatase (Fig. 1A) together with a block (Fig. 1D) in the biosynthetic pathways to the ceramide trihexoside and aminoglycolipid. Alternatively an inhibition of sulphatase (A) coupled with increased activation of the hydrolytic enzymes (B) (ref. 30) and (C) (refs. 30, 31) would also produce a similar composition.

A detailed study of glycolipid metabolism in the kidneys of tumour bearing mice might provide evidence to confirm that there is a definite relationship between the presence of a tumour metabolite and the composition of the glycolipids.

Nomenclature of the Pepsins

The Commission on Enzymes of the International Union of Biochemistry¹ recommends that the highly active pepsin prepared from pig gastric mucosa² which is presumed quantitatively to be the principal pepsin should retain the name originally given to it, pepsin A; the other pig pepsins³.⁴, initially called parapepsins, should be named B. There are three of these minor pepsins, and so Ryle⁵ has subsequently used the name B for the former parapepsin I, C for parapepsin II and D for the third. But this alphabetical system is now inadequate, for B has been found to have two components⁵. Fortunately, none of the groups has used the A, B, C, D nomenclature, so that for the time being these initials, which are also given to the porcine pepsins.

The first sub-division of the human pepsins was into fundic and pyloric enzymes^{6,7}. This differentiation continues to have a physiological validity, but has proved inadequate now that more than two human pepsins are Unfortunately each of the groups which has worked on human material has adopted its own nomenclature so that, for example, the pepsin I of Seijffers et al.8 is evidently the pyloric enzyme described earlier6,7 and its pepsinogen is the PG II of Hanley et al. but probably the P III of Kushner et al. 10. This chaotic situation clearly should be resolved. One of us has worked during the past 17 yr with all the separative techniques that have been used by other workers in this field, and has found that agar gel electrophoresis 10,11 provides the quickest method of scanning an activated gastric mucosal extract for pepsins. It can be the most easily standardized, it gives the sharpest separation of the individual enzymes, it recognizes more pepsins than any other method and, being exquisitely sensitive, it can be carried out with only a small amount

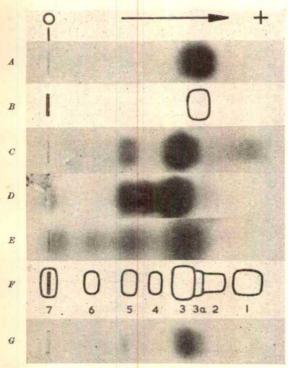

Fig. 1. Agar gel electrophoresis at pH 5·0 of the pepsins. The zymograms illustrate the seven bands that may be seen in normal gastric juice. A, Crystalline swine pepsin; the pepsin is analogous to, but electrophoretically different from, human pepsin 3. B is a drawing of A. C, A human gastric juice showing pepsins 1, 3, 3a and 5. D shows pepsins 2, 3, 3a, 4, 5 and 7. E shows pepsins 3, 5, 6 and 7. F is a drawing illustrating the position of the above zones of proteolytic activity. G, A gastric juice which illustrates more clearly than in C and D that pepsin 3 may sometimes contain a more rapidly moving anodal fraction, numbered 3a.

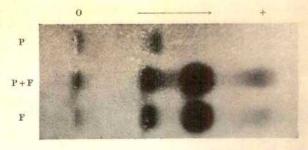

Fig. 2. The pepsins of fundic and pyloric mucosa from a patient with peptic ulcer, displayed after agar gel electrophoresis at pH 5-0. P, Pyloric mucosal extract, showing pyloric pepsins 5 and 7. F. Fundic mucosal extract, showing pepsins 1, 3, 3a, 5 and 7. P+F, A mixture of the two extracts which indicates that the pyloric 5 and fundic 5 enzymes have different mobilities.

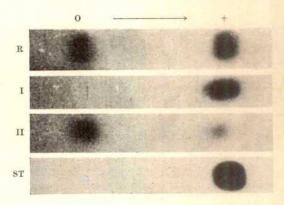

Fig. 3. The proteolytic enzymes of a commercial rennet solution. R, Commercial rennet, showing enzymes in the positions 3 and 7; ST, crystalline swine pepsin, as a standard; I, a chromatographic fraction of rennet containing only calf pepsin 3; II, a chromatographic fraction containing chiefly rennin, which is in position 7.

of enzyme material. It seems only reasonable, therefore, to base a nomenclature on this technique. Anyone working with a gastric fraction can check the behaviour of its pepsins at any stage in a manipulative procedure by agar gel electrophoresis.

With such a nomenclature in mind, more than 200 gastric juice and mucosal extracts from normal subjects and from patients with diseases affecting the gastric mucosa were analysed by agar gel electrophoresis. The variety of patterns displayed reveals that seven proteolytic bands may arise (Fig. 1). Accordingly, it is suggested that these are numbered 1 to 7, in order of decreasing mobility. Fig. 2 shows that there is more than one pyloric enzyme, and that pyloric pepsin 5 is not quite identical with the correspondingly placed band in fundic extracts. Consequently, the number should be prefixed by the initial of the material used: F, fundic; P, pyloric; D, duodenal; M, whole gastric mucosal; J, gastric juice. Fig. 1 shows further that human pepsin 3 and pig pepsin A are not chemically identical, although they appear to be in other respects analogous7,12, so that a further prefix, denoting the animal, could be used: H, human; P, pig; D, dog. Thus HF3 would indicate the principal human fundic pepsin. From published data 10,13, swine pepsin A would on this nomenclature become PF3, and pepsin

Not all these proteolytic bands may indicate an active enzyme, but this is no disadvantage. Thus the 4 band, which we find to be labile, may perhaps be a pepsin inhibitor complex^{12,14}, but it can clearly be demonstrated in gastric juice as a definite biochemical compound and it may well have a physiological significance in this form. This nomenclature would not only locate it accurately for all laboratories, but would describe its transformation into, say, band 3, with economy and precision if the letter I is used for inhibitor; for example, HJ4I→HJ3+I. Future investigation may show that

some of the seven bands have more than one component, and there is evidence in Figs. 1 and 2 that sometimes the 3 band exhibits a slightly faster moving 3a. This, too, may

have a physiological significance.

Until such a nomenclature is widely adopted, it is necessary to record those correlations between the various present nomenclatures that have been established. Thus pepsin C (Ryle) is analogous to pyloric pepsin (Taylor), which is equivalent to pepsin I (Seijffers et al.) and to P III (Kushner et al.). Pepsin B (Ryle) is probably gelatinase (Northrop¹⁵). Pepsin A (Herriott, Desreux and Northrop) is analogous to the fundic pepsin (Taylor), to pepsin II or III (Seijffers et al.) and to P II (Kushner et al.). By the nomenclature suggested here pepsin A would be 3, and pepsin C, 5. The position of pepsin B is not known. As Fig. 3 shows, rennin is 7.

Electrophoretic Separation of the Soluble Proteins of Brucei Sub-group **Trypanosomes**

The brucei sub-group trypanosomes, now assigned to the sub-genus Trypanozoon by Hoare1, have antigens which continually undergo variation and which are apparently soluble proteins localized in the cytoplasm^{2,3}. The nature of the variation is not yet clear and the antigens have not been well characterized, probably because of the lack of a satisfactory method of separation. Chang et al.4 have drawn attention to the advantage to physiology and genetics of efficient separation of protein fractions, and the immunology of trypanosomes would also benefit by such a method, especially with regard to the correlation of their antigenic and enzyme properties.

Attempts have been made for several years in this laboratory to resolve these proteins by zone electrophoresis-using paper, cellulose acetate membrane, polyacrylamide and starch gels, among other media—with a

varying degree of success.

A Trypanosoma brucei Plimmer and Bradford subgroup⁵ strain (a derivative of stabilate⁶ EATRO 691, originally isolated from Glossina pallidipes Austen at Lugala, south-east Uganda7) was passaged with a syringe through Swiss white mice from the closed colony maintained at the East African Trypanosomiasis Research Organization (EATRO) and stabilized at -80° C by the method of Cunningham et al.8. T. rhodesiense strain SS 518, originally isolated from a patient at EATRO, was kept in rats by syringe passage, with intermediate stabilization at -80° C. The two strains were each inoculated intraperitoneally into groups of ten rats. At peak parasitaemia the rats were bled by cardiac puncture;

heparin at a concentration of 4 IU/ml. of blood was used as an anticoagulant. The blood from each group of rats was pooled, agitated with glass beads? for several minutes to remove platelets10 and then decanted. It was then diluted with five times its volume of a solution of 1 per cent glucose in phosphate buffered salt solution (BS-1) (refs. 11 and 12) at 0° C. The trypanosomes were separated from the blood components using the differential centrifugation method of Moulder13 as modified by Simmons et al.14 by the use of cattle serum (which has been found to agglutinate rat blood14,15) instead of rabbit anti-rat serum, until the parasites were microscopically pure.

The trypanosomes were lysed with a third of their volume of water and broken by freezing (ethanol and dry ice) and thawing (ice water) five times, followed by disintegration for 15 sec using the MSE (60 W) ultrasonic disintegrator and freezing and thawing a further five times. The resulting suspension was spun for 15 min at 21,000 r.p.m. (34,000g) with an MSE 'Magnum' refrigerated centrifuge high speed attachment at $2^{\circ}-4^{\circ}$ C and the supernatant was collected. Some of the supernatant was either used immediately for electrophoresis or stored in capillary tubes at -20° C. The remainder was either freeze dried or concentrated overnight at 4° C, over phosphorus pentoxide or using 'Carbowax 20M' (Union Carbide)16, to a protein concentration of 90-120 mg/ml. as determined by the modified biuret method of Ellman¹⁷, and then used for electrophoresis.

The first trials on paper (Knight, R. H., and Simmons, V., unpublished results) did not give any improved resolution over that of Williamson and Dezowitz¹⁸ of four bands and so were discontinued. Encouraging results, however, were obtained using cellulose-acetate

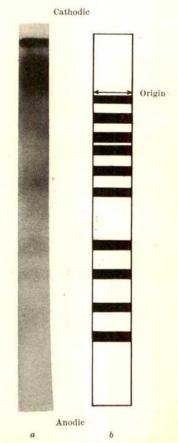

Fig. 1. Cellulose membrane electrophoretic pattern of brucei sub-group trypanosome proteins stained in 1 per cent amido black 10B in methanol/water/acetic acid (50/50/10, y/v). $0\cdot1$ molar tris buffer, pH $8\cdot9$. (a) Photograph of the stained electropherogram. (b) Line drawing of (a).

membranes. Using high resolution tris buffer (LKB Produkter, AB, Stockholm), pH 8·9, a resolution of at least nine bands was obtained (Fig. 1a and b). Although this method was more successful it was discontinued because of the increased resolution which was obtained by gel electrophoresis. Of the gel methods used, disc electrophoresis of Ornestein and Davis^{4,19,20} gave a resolution of eleven components (Fig. 2). Although the method used less material compared with the others and had a better definition, it was discontinued in favour of the starch-gel electrophoresis method of Smithies²¹ which gave us a greatly increased resolution. The starchgel method had an additional advantage in that it

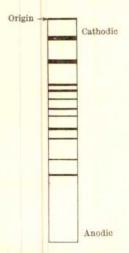

Fig. 2. Line drawing of polyacrylamide disc electropherogram of brucei sub-group trypanosome proteins, stained in 1 per cent amido black 10B in 7 per cent acetic acid. 2.5 per cent large pore gel and 7 per cent small pore gel. See ref. 20 for buffers.

I, EATRO 691; II, normal rat serum; III, T. rhodesiense.

could be sliced into several slabs (four in our case) for staining for different enzymes.

The improved resolution on starch-gel came to our attention through the work of Williamson and Brown³, who had obtained a resolution of eleven anodic components. Our trials were at first unsuccessful because, as we later discovered, the success of the run depended on, among other things, low operating temperatures. We routinely performed the electrophoresis in the refrigerator (and later, in a cold room) at 4° C for 2.5 h at a volt gradient of 8 V/cm. The gel was prepared from hydrolysed starch in the discontinuous glycine–sodium hydroxide–borate buffer system of Fahey and Askonas 22 , but using pH 8-58 instead of 8-9 for the borate buffer. The protein solution was applied to strips of Whatman No. 3 filter paper which were then inserted into the gel. A normal rat serum control was run at the same time and bromophenol blue was applied, as a tracking dye, to a 1 mm hole on one side of the gel. After the run the gel was sliced horizontally, one slice stained for proteins (amido black 10B) and the remainder for enzymes. We found that freeze-drying denatured the proteins, and concentration, although it improved the definition, introduced "necking" and streaking of the proteins. In addition, some of the cathodic and fast moving components (5', 22, 23, 24) disappeared on concentration with 'Carbowax 20M'. We therefore used unconcentrated material, usually freshly prepared but occasionally after storage for 24 h at -20° C, which did not affect the separation pattern.

Fig. 3 shows the resolution of a normal preparation in which at least twenty-two components can be detected. Using the R_F concept, introduced by Chang et al. and defined as the mobility of each band expressed as a percentage of the mobility of the tracking dye, it is possible to compare the reproducibility of the runs. Fig. 4 shows a scale drawing of the resolved components of Fig. 3

(Fig. 4B) and another preparation (Fig. 4A). Each R_F is ±0.5 of the true value to allow for errors in measurement for an error of 0.5 mm introduces an error of 0.5 in the R_F value in a 10 cm run (the usual distance travelled by the dye during the run). The resolution is reproducible to within $1 R_F$ value. Not all components appear on each separation, and inspection of Fig. 4 suggests that there are at least twenty-nine components.

The five cathodic components and three or four anodic components which have a mobility greater than that of rat albumin are particularly interesting. They do not seem to have been reported before, although we have found them in all our preparations (although not all components on each preparation). Some of these components have the same mobility as the rat serum components (the notation on rat serum proteins is that of Beaton et al.23), but two observations suggest that they are not contaminants from the serum. First, trypanosomes separated by the method we used are about 99 per cent pure14 and the concentration of the serum proteins is so low that they are unlikely to be detected by amido black 10B. Second, staining for various enzyme activities (our unpublished work) shows that bands of the same mobility do not correspond in enzyme activities. Although the separation is high, some of the bands still remain relatively complex. Staining for dehydrogenases, for example, shows that some of the bands have multiple enzyme function which implies that they consist of several enzymes of the same mobility. With this improved resolution, however, it will probably now be possible to correlate enzyme and antigenic properties of some of these components.

New Aminoquinoline with Schistosomicidal Activity

DURING routine testing of compounds, we have discovered schistosomicidal activity in a series of 5-aminoquinolines. Many compounds with this general formula were made and tested and some were found to have activity, but one compound was outstanding. This was 6-chloro-5-βdiethylaminoethylamino-8-methylquinoline.

$$\begin{array}{c} \text{NHCH}_2\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2 \\ \\ \text{Cl} \\ \\ \text{CH}_3 \end{array}$$

The compounds were tested against a strain of Schistosoma mansoni maintained in Australorbis glabratus, originally obtained from Dr O. D. Standen of the Wellcome Institute. All routine tests were carried out in mice. The animals were infected by subcutaneous injection of an estimated 100 cercariae/mouse, because this method was found to be quicker and to give a higher rate of recovery of adult worms than percutaneous infection. Dosing was started on the fifty-sixth day after infection. The mice were given one oral dose daily for 4 consecutive days, starting at 500 mg/kg if the acute LD_{50} was over 1,000 mg/kg, and one-third to one-quarter of the LD_{50} if this was below 1,000 mg/kg. Further testing was carried out at reduced levels when schistosomicidal activity was found, to determine the lower limit of activity. Finally, comparative tests were carried out, using fractions of the subchronic LD_{50} (that is, the dose that killed 50 per cent of the mice given daily doses for 4 successive days) to establish the most active compounds and therapeutic ratios. The mice were killed 3 weeks after the completion of treatment and the numbers of dead and living worms recorded. This time interval was selected because lucanthone, which was used as a reference drug in the comparative tests, did not kill worms before this time, although the aminoquinoline killed them in 7 days.

6-Chloro-5-β-diethylaminoethylamino-8-methylquinoline was found to be active at 30 mg/kg. When the dose was expressed as a fraction of the subchronic LD_{50} we found that the compound killed 90 per cent of the worms at one-eighth of the subchronic LD_{50} (300 mg/kg) while lucanthone killed 70 per cent or less at its subchronie LD_{50} (200 mg/kg).

Acute toxicity studies have shown that the compound has little toxicity in mice, rats, guinea-pigs, rabbits and monkeys. In cats and dogs, however, the compound produced thoracic lesions consisting of peribronehial and pulmonary oedema, a gelatinous exudate around the pericardium and oesophagus, and submucosal oedema and inflammation in the muscle of the bladder. The marked species difference in susceptibility is indicated by the fact that the oral LD_{50} in the cat is 10 mg/kg, while in the rat it is 900 mg/kg.

Chronic administration to mice and rats produced reversible enlargement of the bladder and liver, without any histopathological changes related to treatment at a dose to mice of 200 mg/kg a day for 30 days, but in rats this regimen produced some bladder change. Cats given 4 mg/kg once or twice daily on successive days died within 4 days, but when given two doses on 1 day only there were survivors. The thoracic lesions could be detected radiographically 48 h after dosing, and in the survivors they were shown to be completely resolved 8 Bladder damage was, however, more perdays later. sistent.

Dogs were less susceptible than cats. Mongrels tolerated 80 mg/kg daily for 30 days, and showed only some bladder damage. In beagles, however, 100 mg/kg once or 20 mg/kg twice a day was fatal to some. In these dogs the lesion was oedema of the lungs, with little or no bladder damage.

Monkeys tolerated 120 mg/kg daily for 5 days without showing any gross or histopathological lesions.

No explanation has yet been found for these differences in species susceptibility, and it is impossible to forecast how man would respond to the compound. Unless metabolic studies help to explain these species differences it is likely that this compound will be regarded as too toxic for clinical trials in man, although it could have high activity in human schistosomiasis.

PATHOLOGY

Antigen Induced Release of Histamine and SRS-A from Human Lung passively sensitized with Reaginic Serum

REAGINS are the skin sensitizing antibodies believed to be responsible for the clinical symptoms of hay fever and allergic asthma in man. They differ from precipitating antibodies in that they bind only to tissues of primate species1, are heat labile and do not form precipitate or fix complement on mixing with specific allergen in vitro2. As a consequence of these properties, the classical method of Prausnitz and Küstner³ (the PK test) remains the only reliable technique for measuring reagin activity. In this test allergic serum is injected into the skin of a nonsensitive human and a weal and flare reaction develops after challenge with antigen. The danger of transmitting infective hepatitis virus to the normal recipient in the PK test has led to many attempts, usually unsuccessful, to develop alternative in vitro procedures. Van Arsdel and Sells4, however, with human leucocytes, and Goodfriend et al.5 with monkey lung tissue, have demonstrated satisfactory passive sensitization after incubation with human allergic serum by measuring histamine release after addition of antigen. This communication describes an in vitro technique involving the passive sensitization of human lung tissue with serum from allergic individuals. The release of histamine and "slow reacting substance of anaphylaxis" (SRS-A) after exposure to specific antigen(s) has been used to measure the antigen-antibody reaction.

Fresh specimens of macroscopically normal human lung were obtained after surgery for carcinoma of the lung. The specimens were transported to the laboratory in ice-cold oxygenated Tyrode solution. The primary bronchi and blood vessels were dissected out and about 12 g of lung parenchyma was chopped finely with sharp seissors in a loz. 'Universal' bottle. The chopped tissue was mixed in about 200 ml. of cold Tyrode solution, filtered through gauze, washed thoroughly and drained of excess fluid. Portions (400 mg) of the chopped washed tissue were suspended in 4 ml. volumes of sera from allergic patients and diluted 1:10 with Tyrode solution or in Tyrode solution alone. Chlortetracycline (0.01 mg/ml.) was added to each tube as a bacteriostat. All tubes were incubated overnight at room temperature, followed by 1 h at 37° C. The samples were then washed thoroughly, to remove excess antibody before incubation at 37° C for 15 min, with 4 ml. of Tyrode solution alone or Tyrode solution containing an extract of cocksfoot pollen antigen(s). The extraction procedure was as follows. 1 g of dry cocksfoot pollen was mixed for 1 min at room temperature with 10 ml. of glass distilled water. suspension was immediately filtered through 'Celite', the filtrate discarded, and the pollen further extracted for

1 h with 10 ml. of Coca's solution from which the phenol was omitted. The suspension produced was filtered through 'Celite' and the filtrate was sterilized by membrane filtration. By an aseptic technique the sterile extract was bottled in 5 ml. portions and stored at -20° C. Before use the pollen extract was diluted to 10^{-2} with Tyrode solution.

After incubation of the lung samples with antigen the supernatants were removed, placed in ice, and assayed for histamine and SRS-A on the same day using the isolated guinea-pig ileum bathed with Tyrode solution containing atropine sulphate (10-6 molar). When assaying SRS-A, mepyramine maleate (10-6 molar) was also added to the bathing fluid to prevent interference from the histamine in the samples. Histamine content was expressed as histamine base and SRS-A in arbitrary units with reference to 0.05 ml. of a standard sample of freeze-dried perfusate. The total histamine content of the lung tissue was determined as follows: duplicate lung samples were treated as experimental samples except that after washing to remove excess antibody they were heated in 10 ml, of Tyrode solution for 5 min in a boiling water bath and then left for 10 min at room temperature before the supernatants were removed for assay.

Sera from twelve patients exhibiting hay fever and allergic asthma provoked by mixed grass pollen have been studied. Sera were obtained using standard aseptic techniques and were stored in 2.5 ml. portions at -70° C without preservative. Small amounts of histamine and SRS-A were found in the supernatants of the two types of control tubes containing (a) sensitized lung tissue "challenged" with Tyrode solution only and (b) unsensitized tissue "challenged" with antigen (Table 1). Consequently, we have adopted the following criteria to denote sensitization of lung tissue by the serum, that is, that in at least two experiments with different lung tissue the antigen induced histamine and SRS-A release should be at least 2.5 times the control values. By these criteria three of the sera caused sensitization and a further three produced excellent sensitization with histamine and SRS-A release from five to twenty-five times the control values. One of the latter sera (from patient P.St.) has been used extensively in our experiments (Table 1). The clinical data give no obvious reason for the differences in the sensitizing activity of serum from P.St. compared with the inactive serum of, for example, R.A. Both patients had severe hay fever and moderately severe asthma confirmed by aerosol provocation as well as skin tests and had not been desensitized. It is interesting that our colleagues have found that both sera were able passively to sensitize "reactive" leucocytes for histamine release on antigen challenge. Similarly leucocytes from both sera released histamine on direct challenge with cocksfoot antigen. Levy and Oslers found that only one in every five non-allergic individuals provided suspensions of leucocytes suitable for passive sensitization with reaginic serum. Active sera from different individuals, however, could sensitize the "reactive" leucocytes from this small

proportion of donors. Our results imply the opposite, that is, that only certain sera will passively sensitize human lung, but that active serum P.St. passively sensitized all but three samples of lung tissue from thirty patients. There is a marked specificity in a reaginic antibody-human tissue reaction the basis of which is unknown.

Results of ten experiments with different lung tissue but the same serum (P.St.) at a dilution of 1:40 are shown in Table 1. Release of histamine from sensitized lung after antigen challenge was 11.3 times the mean control values and the antigen induced SRS-A release was 8.3 times the mean control values. These increases were very significantly different from the controls (P < 0.001)according to Student's t test.

Brocklehurst⁷ studied the release of these same pharmacological mediators of anaphylaxis during perfusion of an actively sensitized human lung segment (200 g) removed from a woman allergic to birch tree and timothy grass pollen. After challenge with these antigens, totals of 1,425 ng of histamine/g lung and 135 U of SRS-A/g of lung were found in the perfusate after 78 min. These amounts were about half those from passively sensitized lung during 15 min in the experiments reported here (3,024 ng of histamine/g of lung and 298 U of SRS-A/g of lung).

In an attempt to verify the role of reaginic antibody in these experiments, equal volumes of the human allergic serum from patient P.St. were heated at 56° C for varying The heated sera were then incubated with portions of human lung tissue as already described.

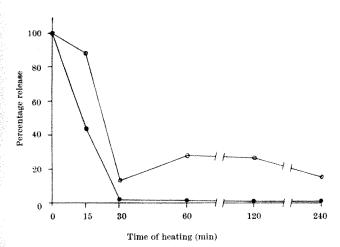

Fig. 1. Effect of subjecting serum to a temperature of 56° C for varying times and the ability of the serum passively to sensitize human lung.

◆. Histamine; ○, SRS-A.

Results are shown in Fig. 1. Releases of histamine and SRS-A are shown as percentages of the release obtained after sensitization with unheated serum and have been corrected for the small spontaneous "leakage" of histamine and SRS-A in control samples. Each point on the graph is the mean of triplicate samples. Heating the serum for 30 min at 56° C substantially destroyed the capacity of the serum passively to sensitize human lung. This suggests that the sensitizing antibodies were reagins.

In summary, a technique for passive sensitization of human lung with homologous reaginic serum is described and its efficacy demonstrated. Experiments with heated serum provided evidence that the sensitizing antibodies were reagins. Three out of the twelve sera from allergic individuals were particularly potent and a further three gave satisfactory sensitization. Thus not all sera from allergic patients would sensitize human lung, although clinical data gave no obvious reason for the differences in the sensitizing activities of the sera. The technique described is not therefore an acceptable substitute for the PK test. With suitably potent reaginic sera, however, this technique can be used as an in vitro model of an immediate hypersensitivity reaction in the lung.

We thank Mr Gordon Jack for specimens of human lung, Dr Geoffrey Taylor for some serum samples, Drs J. S. G. Cox, R. E. C. Altounyan and W. E. Brocklehurst for encouragement and advice, and Mrs S. Twiss and Mrs P. M. Bryson for technical assistance.

CYTOLOGY

In vitro Production of Meiosis Inducing Substance by Nerve Extract in Ovary of Starfish

It is well known that spawning can be induced by injecting a water extract of radial nerves into the coelomic cavity of mature male or female starfish1-4. The coelomic fluid of the starfish, Asterias amurensis, at the time of natural spawning shows gamete shedding activity similar to that of nerve extracts, and so the active substance seems to be liberated from nerve into the coelomic cavity, where the gonads are suspended. This gamete shedding substance is a polypeptide^{3,6} and seems to be a neurosecretory substance^{3,7}. As well as inducing spawning, it may act directly on the ovary and induce occyte maturation7,8, for in A. amurensis local application of nerve extract to an isolated ovary induces maturation of oocytes located only in the treated portion, and isolated oocytes in calcium free sea water containing nerve extract undergo meiosis*. Oocytes of A. amurensis usually undergo meiosis when isolated in normal sea water but not in calcium free sea

In the case of Asterina pectinifera most of the oocytes isolated in sea water fail to undergo meiosis, and addition of nerve extract has little effect in inducing maturation. We found, however, that these oocytes do undergo meiosis when transferred to sea water containing nerve extract in which ovarian fragments have spawned heavily 1-3 h previously (Fig. 1). This suggests that some active substance is liberated into the medium from the ovary. Breakdown of follicles around the oocytes was clearly observed when the isolated oocytes were transferred into the active medium.

These active media were subjected to gel filtration on a column of 'Sephadex' in an attempt to separate a meiosis inducing substance from the gamete shedding substance of nerves which had been introduced into the media. Asterina ovaries were weighed and placed in artificial sea water containing nerve extract (200 mg of wet ovary/ ml. of sea water containing 100 µg of lyophilized nerve). The nerve extract was prepared by a method described before⁵. After 2.5 h these mixtures of ovary and nerve extract were centrifuged at 3,500 r.p.m. for 10 min. The supernatants induced meiosis even at ten- to twenty-fold dilution. Samples (3 ml.) of each supernatant were applied to a column of 'Sephadex G-15' (1.4 × 42 cm) equilibrated with artificial sea water (pH 8·2-8·3), which was also used as eluant. The fraction size was 5 ml. and the flow rate was 30 ml./h. Samples in small Petri dishes (1.5 ml. each of test solution) containing either isolated oocytes or ovarian fragments were used to assay for maturation and spawning. Observations were made after 1 h. Fig. 2A shows a representative result. After gel filtration the meiosis inducing substance did not appear in the same fractions (fraction No. 21-23) as the gamete shedding substance (fraction No. 5-7). It was interesting that the fractions which induced meiosis also induced spawning (fraction No. 21-23).

For comparison, 3 ml. of sea water containing nerve extract (100 µg/ml.) and 3 ml. of the supernatant (centrifuged at 31,000g for 1 h) of ovary homogenate (200 mg of wet ovary/ml. of sea water) were also gel filtered on the same column of 'Sephadex G-15' and respective fractions were assayed in the same manner. No fractions which induced meiosis, however, were obtained by gel filtration of either nerve extract or ovary extract (Fig. 2B and C).

These facts suggest that the gamete shedding substance of neural origin acts on the ovary and induces the production of a new substance which is, in a true sense, a meiosis inducing factor and probably also a spawning inducing factor. In other words, a polypeptide, probably a neurosecretory substance, derived from nerves seems to act on the ovary, the target organ, and there to produce a second active substance(s) which is responsible for maturation and spawning. We propose, to avoid confusion, that the second substance of ovarian origin is called "meiosis inducing substance" (MIS), for the active principle of neural origin has been called "gamete shedding substance" (GSS).

Some investigations of the nature of MIS gave the following results. First, heating in boiling water for at

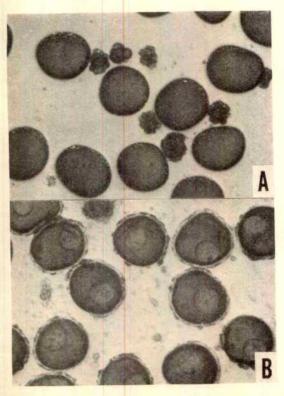

Fig. 1. Induction of meiosis of isolated Asterina occytes, A, Oocytes in the supernatant of mixture of ovary and nerve extract. B, Control in sea water. Observations were made after 1 h. Note breakdown of germinal vesicles and follicles in A.

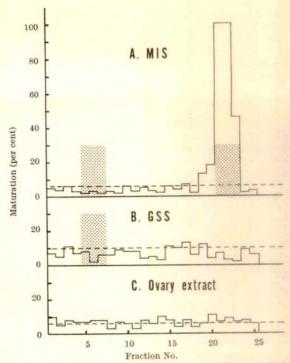

Fig. 2. Meiosis inducing activity of fractions obtained by gel filtration of supernatant of (A) mixture of ovary and nerve extract (MIS), (B) nerve extract (GSS), and (C) ovary extract on 'Sephadex G-15'. Broken lines represent percentages of maturation in sea water (control). Dotted area represents the fractions having gamete shedding activity.

least 30 min had no effect on its maturation and spawning inducing activities. Second, after successively shaking the active supernatant with ether, benzene and petroleum ether, all these activities remained in the aqueous phase. Third, treatment with trypsin (Sigma, 10,000 U/mg), chymotrypsin (Tokyokasei, 22,000 U/mg), pepsin (Sigma, 2,800 U/mg) for 2 h at 25° C and finally pronase P (Kakenkagaku, 45,000 PUK/g) for 5 h at 37° C had little effect on its meiosis and spawning inducing activities, whereas the spawning inducing activity of the nerve extract was completely removed by the same treatments with these proteolytic enzymes (Table 1). The final concentration of the enzymes was 0.01 per cent and the pH of the reaction mixtures was 2.0 for pepsin and 7.9 for the other enzymes. These results indicate that MIS is heat stable, water soluble, not a breakdown product of the gamete shedding substance, and probably not a peptide.

Table 1. EFFECT OF PROTEOLYTIC ENZYMES ON INDUCTION OF MEIOSIS AND SPAWNING BY MEIOSIS INDUCING SUBSTANCE AND GAMETE SHEDDING SUBSTANCE IN Asterina pectinifera

Enzymes		inducing ce (MIS)	Gamete substan	Sea water (control)	
24-0-	Spawning	Maturation (per cent)	Spawning	Maturation (per cent)	(per cent)
Trypsin	+	98	-	6	4
Pepsin	+	99	_	9	. 9
Chymotrypsin	+	98	_	11	12
Pronase P	+	100	_	10	4

Production of meiosis inducing substance in the isolated ovarian fragments under the influence of nerve extract was also found in other starfish species, such as Coscinasterias acutispina and Asterias amurensis. Although the nerve extract of A. amurensis failed to induce spawning in A. pectinifera, the meiosis inducing substance of A. amurensis induced maturation of isolated oocytes and spawning of A. pectinifera. In other words, although there are some species differences among the gamete shedding substances of nerves, this is not observed among the meiosis inducing substances of ovaries. Indeed, the meiosis inducing substance of one species acts equally well on the isolated oocytes of other starfish species without exception as so far tested.

Spatial Distribution of Old and New Chromatid Sub-units and Frequency of Chromatid Exchanges in Induced **Human Lymphocyte** Endoreduplications

In Vicia faba, chromatids are formed by two functional sub-units that replicate during interphase and segregate at anaphase together with their replicas1. This has been confirmed in other organisms2-6 and interpreted on the basis of a uninemic chromosome model and semiconservative DNA replication6.

Old and newly synthesized chromatid sub-units show a well defined spatial relationship in spontaneous and induced endoreduplications7,8. We have therefore sought further data on the spatial distribution of newly synthesized chromatid sub-units in diplochromosomes and quadruplochromosomes of endoreduplications induced by desacetylmethylcolchicine ('Colcemid', Ciba)'. have also sought to estimate the types and frequency of sister chromatid exchanges in human material.

Blood was obtained from two normal male donors and cultures were set up by a modification of the technique of Moorhead et al.10. On the third day of incubation, 3H-thymidine (specific activity 5 c./mmole) was added to the cultures at a concentration of 1 µc./ml. of culture medium. After 6 h, 'Colcemid' was added to a final concentration of 0.5 µg/ml., and 2 h later the radioactive medium was removed and the cells were resuspended in fresh medium containing 0.02 ml. of phytohaemagglutinin and 0.1 µg of 'Colcemid'/ml. and carrier thymidine at a concentration 100 times greater than that of the 3H-thymidine in the discarded medium. The cultures were incubated for a further 48 or 72 h and chromosome preparations were made by the air drying technique.

The slides were stained with acetic orcein for the cells to be photographed before autoradiography. Cultures collected 48 h after the change of medium showed only single endoreduplications (about 4 per cent of all the metaphases), while those collected after 72 h contained both single (8 per cent) and double endoreduplications (0.6 per cent). The slides were then coated with Kodak AR-10 autoradiographic stripping film, exposed for 6 or 10 days and developed in Kodak D-19b for 5 or 2 min,

respectively.

Ninety per cent of the endoreduplications were labelled and almost all of these showed diplo- or quadruplochromosomes with only two labelled chromatids. This indicated that they had taken up 3H-thymidine during the first DNA synthetic period of the process of endoreduplication (ES₁)^{7,11}. One hundred and thirty single and ten double endoreduplications showing fairly uniform chromatid labelling were analysed as follows. A schematic drawing was made of all diplo- or quadruplo-chromosomes

showing well spread and overlap-free chromatids from examination of the unlabelled photographs. The autoradiographs of these chromosomes were analysed and the labelling patterns were marked in the drawings. We studied 1,273 diplochromosomes and sixty quadruplochromosomes.

Of the 1,273 diplochromosomes analysed, 850 gave information on the distribution of old and new chromatid sub-units. As shown in Fig. 1a and indicated in Table 1, most of these diplochromosomes were labelled over the two external chromatids (outer/outer labelling pattern), while only a few had one external and one internal chromatid labelled (outer/inner pattern), and even fewer had both the internal chromatids labelled (inner/inner pattern). The only labelled DNA was that of chromatid the two sub-units synthesized during ES1, and so a random spatial arrangement of old and new sub-units after the second replication in diplochromosomes should result in a 1:2:1 ratio of outer/outer, outer/inner and inner/inner patterns of labelling. Consequently, the observed frequencies of these patterns (see Table 1) show clearly, in agreement with previous reports7,8, that the old and new chromatid sub-units are not distributed at random. The few instances of outer/inner and inner/

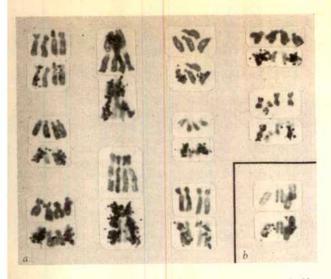

Fig. 2. a, Autoradiographs of quadruplechromosomes from double endoreduplications labelled during ES_1 with *H-thymidine. The label is chiefly in the internal chromatids of the two outermost chromosomes. b, Acentric fragment showing the same labelling pattern of the normal chromosomes shown in a.

inner patterns are probably explained by technical artefacts.

The 423 diplochromosomes showing chromatid exchanges could not give clear information on the distribution of old and new chromatid sub-units, but on the average even in these diplochromosomes the external chromatids showed larger labelled areas than the internal ones.

Our findings in double endoreduplications provide additional evidence for the non-random spatial arrangement of old and new chromatid sub-units. The quadruplo-chromosomes labelled during ES_1 showed only two

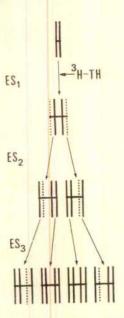

Fig. 3. Schematic representation of the spatial relationship of old and new chromatid sub-units during successive replication cycles leading to single endoreduplication (after ES_s) and double endoreduplication (after ES_s). Each chromatid is represented by two sub-units which are drawn as solid or broken lines to indicate whether they are unlabelled or labelled. The centromere is represented by a transverse line. ES_1 , ES_s and ES_s are respectively the first, second and third DNA synthetic periods. "H-thymidine ('H-TH) was present only during ES_1 , and so only the sub-units synthesized during this period are labelled. The figure shows that if at each replication the new sub-units are synthesized on the outside of the old ones, the labelled sub-units will be part of the external chromatids of the diplochromosomes (after ES_s) and of the internal chromatids of the outermost chromosomes of the quadruplochromosomes (after ES_s).

brackets.

labelled chromatids. These were the inner ones of the two outermost chromosomes in all the quadruplo-chromosomes, which did not show chromatid exchanges (Fig. 2a), but even when exchanges had occurred the two inner chromatids of the outermost chromosomes generally showed the largest labelled areas. A preferential pattern of labelling was therefore also evident in quadruplo-chromosomes where two cycles of DNA replication had

taken place after labelling in ES1.

As previously pointed out 7.8, the labelling pattern observed in the diplochromosomes could be explained if at each replication the new DNA sub-units of each chromatid are synthesized on the outside of the old ones. Fig. 3 shows that this explanation fits also the described quadruplochromosomes labelling pattern. Walen has suggested that the centromere could prevent replication between the old sub-units and thus be responsible for the peripheral location of those newly synthesized. We have found, however, in a few endoreduplications, acentric fragments showing the same distribution of labelling found in normal chromosomes (for example, Figs. 1b and 2b). This suggests that some other feature of the chromosome structure is responsible for this phenomenon.

Sister chromatid exchanges in human mitotic chromosomes have been observed 2,5,11 , but an estimate of their types and relative frequencies has not been given. In the diplochromosomes labelled during ES_1 it is possible to score twin and single exchanges, that is first and second cycle exchanges after labelling (compare ref. 3). Our findings in 1,273 diplochromosomes (2,546 single chromosomes) are summarized in Table 2. This shows that the frequency of exchanges per chromosome and cell cycle decreases from groups A to G suggesting that this frequency is related to the mean chromosome length.

Several exchanges appear to have occurred at the centromere region. These have been listed separately in Table 2 because they could be mimicked by a morphologically non-perceptible twist at the centromere. Marin and Prescott¹², however, have shown that in Chinese hamster cells true centromere exchanges are very frequent, and this might be true also in our material.

Finally, Table 2 shows that the ratio of twin to single exchanges is quite close to 1:2, in keeping with Taylor's

findings in plant material4,6.

PHYSIOLOGY

Surface versus Intracellular Polarization of Cortical Cells

Although it is almost 100 yr since the original report of Fritsch and Hitzig1, many of the effects of direct current stimulation (polarization) of the surface of motor cortex on cellular activity remain unclear. Electrophysiological research has shown that surface anodal polarization increases while surface cathodal polarization decreases the rate of discharge of cortical cells2-5. These results have been interpreted in terms of a model developed to explain the effects of direct current applied extracellularly on isolated nerve terminals^{6,7}. In its simplest form, increases and decreases in discharge rate have been related to polarization induced displacements in membrane potential of cells subjected to a longitudinal potential gradient 8-12. Presumably some fraction of diffuse extracellular applied current enters areas of superficial membrane close to the focal polarizing electrode. The chief effect of this current. however, is exerted as it leaves from distant parts of the excitable membrane. Accordingly, in the cortex, a surface anode provides inward current as it enters superficial dendritic regions of vertically oriented cells which subtend several cortical layers. At the same time the anode generates an outward depolarizing current as it passes out through deep-lying areas of excitable membrane in the soma or axon-hillock region of the cell. The sequence of events is presumably reversed when a surface cathode is used.

No cell in the cortex, however, can be assumed to exist in true isolation, and certainly the prototype cell for the hypothesis outlined here—the pyramidal type cell-

forms only a small segment of a synaptically connected neural assembly comprised of multiple vertical links¹³. Changes that occur in cell behaviour during polarization as a result of secondary synaptic effects have been considered 12,14,15, but never demonstrated. The purpose of this communication is to show that some of the changes observed in cell activity during polarization result from indirect effects mediated by presynaptic sources.

The results are based on intracellular responses obtained from identified pyramidal tract cells (PT) and unidentified cells in the motor cortex of the cat. Recordings were made from unanaesthetized preparations 6-12 h after transection of the midbrain 16. Polarizing currents were applied to the cortex through a silversilver chloride electrode connected to the pial surface through a pool of 0.9 per cent sodium chloride and a 0.5 mm diameter opening in the base of a plastic cup used to stabilize the cortex. The path for the return of the current was provided by a diffuse electrode in the mouth. Recording micropipettes (3 molar potassium chloride) were inserted through the opening used apply polarizing currents. Intracellular stimulation was accomplished with a modified Wheatstone bridge¹⁷.

The effects of different intensities of anodal polarization are illustrated in Fig. 1A, 1-4. As in the case of most cells that were affected by polarization, the average rate of cell discharge increased as a function of stimulus intensity. In many cells, however, there was a pause after the initial discharge evoked at the onset of polariza-This cessation of activity was succeeded by a resumption of spike discharge that continued at an increased rate until the current was turned off.

To exclude the possibility that the cessation of cell discharge was elicited by a direct effect of current on the postsynaptic membrane, different intensities of transmembrane polarization were tested (Fig. 1C, 1-4). At each intensity, intracellular stimulation evoked rhythmic cell firing without any indication of a pause in cell activity comparable with that seen during surface polarization.

Results of transmembrane stimulation indicate that the pause in cell discharge during surface polarization originates either from a direct but remote effect of extracellularly applied current on the postsynaptic membrane, or from an indirect effect mediated by presynaptic elements. A close examination of the pause in cell discharge revealed a perceptible downward displacement in the polarization potential induced by polarization immediately after the initial cell discharge (see Fig. 1A, 2-4). Often small prepotentials were detectable during this period, suggesting that there was an active inhibition of the process of spike generation. The hyperpolarizing displacement in the potential induced by polarization was not apparent in extracellular records. Rather, the potential recorded from near the cell after the onset of surface polarization showed a smooth exponential rise to the final steady state (compare Fig. 1D with 1A, 4).

To determine whether the inhibitory pause was dependent on the level of the postsynaptic membrane potential, surface polarization was applied during intracellular hyperpolarization of the cell membrane which produced two important changes in the discharge pattern evoked by anodal polarization. The rate of discharge was reduced. Conversely, a greater number of discharges appeared during the period usually occupied by the inhibitory pause (compare Fig. 1A, 4 with 1B). This seemingly paradoxical effect would be expected if the inhibitory pause results from an underlying inhibitory

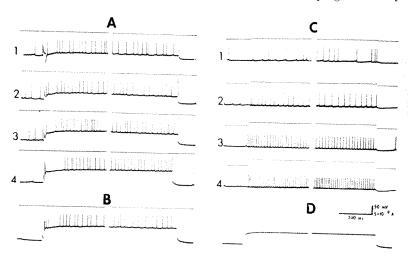

Fig. 1. Comparison of surface and intracellular polarization effects on a cell in the motor cortex. All responses are from the same cell. A, Different intensities of surface anodal polarization: 1, 25 μamp; 2, 50 μamp; 3, 75 μamp; and 4, 100 μamp. B, Effect of surface anodal polarization (100 μamp) during intracellular membrane hyperpolarization. C, Different intensities of intracellular polarization. Current trace shown in top trace, cell response to depolarizing currents shown in bottom trace. D, Extracellular response during surface anodal polarization (100 μamp) recorded after withdrawal of electrode from cell. Approximately 8 sec of surface or intracellular polarization deleted from each response. Deleted portion signified by separation in continuous trace. Cell depth 1-53 mm, action potential 69 mV and average resting potential 60 mV. Voltage and time calibration refers to all records; current calibration refers to records shown in C.

postsynaptic potential (IPSP). Intracellular hyperpolarization reduces the efficiency of the IPSP by driving it closer to its equilibrium potential. Membrane hyperpolarization only partially restricts the excitatory drive on the cell induced by polarization, and so more discharges can occur during the inhibitory pause.

The cell shown in Fig. 1 was one of a group, not from the pyramidal tract, which exhibited complex synaptic patterns of activity following stimulation of nucleus ventralis lateralis (VL) or the peduncle (PED) (Fig. 2A). To determine whether synaptic activity could modify the effects elicited by a surface anode on cell discharge, VL or PED stimulation was applied during surface polarization (Fig. 2B). Both excitatory and inhibitory potentials were apparent during polarization, and while the total duration of the IPSP was shortened its amplitude was unchanged. Spike discharges induced by surface polarization were completely abolished during the initial period of the IPSP.

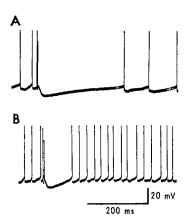

Fig. 2. Effects of surface anodal polarization on inhibitory post-synaptic responses. A, EPSP-IPSP sequence evoked by stimulation of the pyramidal tract (PED). B, Same sequence during surface anodal polarization (100 μ amp). Responses from the cell shown in Fig. 1.

A comparison of the results of intracellular and surface polarization indicates that the inhibitory pause probably does not result from a direct effect of extracellularly applied current on the postsynaptic membrane. Instead, the evidence suggests that the inhibitory pause represents a synaptically induced event. The inhibitory pause is characterized by a movement of the membrane potential in a hyperpolarizing direction. Prepotentials without associated spike discharge often occur during this period. The effects of intracellular hyperpolarization indicate that the inhibitory pause is dependent on the postsynaptic membrane potential in a manner analogous to the dependence of identified IPSPs on membrane potential. Finally, cell discharge elicited by surface anodal polarization can be inhibited by IPSPs evoked by VL or PED stimulation.

These results are an example of an effect of surface polarization that cannot be attributed to the direct effect of extracellularly applied current on cortical cells. Recognition of this example was simplified by the fact that excitatory rather than inhibitory events have traditionally been associated with the action of surface anodal polarization. Both excitatory and inhibitory potentials, however, occur in cortical cells after stimulation of the cortex with short duration pulses 18-22. Often the threshold for surface induced synaptic stimulation is lower than that for direct stimulation of cortical cells22. In all instances where the inhibitory input has been carefully studied, it has been necessary to postulate a disynaptic or polysynaptic intra-cortical pathway²³. The cells or fibre system which produce the inhibitory pause may belong to this general intracortical inhibitory system.

The immediate consequence of these results is to reopen the question as to what part of the other effects of surface polarization attributed to a direct effect on cell behaviour is caused instead by indirect or synaptic effects. The results also suggest that the interpretation of all effects of polarization in terms of a potential difference between dendrite and axon is based on an oversimplified model which neglects important secondary synaptic effects in an interconnecting system of cells.

I thank Dr H. Jasper for his support and encouragement. This research was supported by the Medical Research Council of Canada, a grant (to H. Jasper) from the Committee on Psychobiology of the US National Science Foundation and a US National Institute of Mental Health postdoctoral fellowship.

Adrenergic Transmission in Small Arteries

Transmission of excitation from nerve to vascular smooth muscle is poorly understood. Bevan and his co-workers1,2 were unable to detect any change in membrane potential in pulmonary arterial muscle after sympathetic nerve stimulation, although contraction occurred. Steedman³ found that sympathetic nerve stimulation increased the firing of action potentials in rat mesenteric arterial muscle, as did nerve stimulation of rabbit portal vein muscle4. Only in the arterial muscle of one species—the guinea-pig -has a discrete depolarization, reminiscent of the excitatory junction potential (EJP) recorded from other smooth muscle, been reported. The following data show that EJPs can be elicited from muscle cells in several arteries of the rabbit.

Arterial segments were removed from rabbits, placed in a horizontal organ bath and perfused with Krebs solution (at 36°-38° C) using the method of de la Lande and Rand⁶. Three arteries were used: the ear artery;

Table 1. EXCITATORY JUNCTION POTENTIALS OF RABBIT ARTERIAL MUSCLE IN RESPONSE TO PERIARTERIAL NERVE STIMULATION

	Max. membrane	Excitatory	unction potential
Artery	potential $(\mathbf{mV} \pm \mathbf{S}. \mathbf{D}.)$	Delay	Max. size*
Branch of	(mv ± 5.D.)	(msec)	$(mV \pm S.D.)$
posterior	54.1 ± 4.2	16-40	4.0 ± 0.8
mesenteric Ear	(n=9) $62\cdot 4 + 4\cdot 4$	12~24	(n=8) 6·1 ± 4·9
	(n=9)		(n=8)

* For fully facilitated EJPs. Two cells were lost before facilitation was

the first side branch leaving the posterior mesenteric artery; and a caecal artery. Membrane potentials were recording intracellularly using glass microelectrodes filled with 3 molar potassium chloride (resistance > 20 m Ω) and suspended in a way previously described, a Nikon Kohden preamplifier (grid current $< 10^{-11}$ amp) and a Tektronix $502\hat{A}$ oscilloscope. The periarterial nerves were stimulated by means of a pair of platinum electrodes partially embedded in the wall of a hole in an 'Araldite' block through which the proximal part of the artery was inserted.

EJPs to periarterial nerve stimulation were recorded from muscle cells in five mesenteric arteries, three ear arteries and one caecal artery. The mean maximum membrane potentials (E_{max}) were high (Table 1) and stable compared with the values reported for other vascular smooth muscles. With the exception of the rabbit pulmonary artery^{1,2} the mean E_{max} for rabbit, rat and guinea-pig arteries and veins^{3-5,7,8} varied between 33 and 39 mV and the membrane potential fluctuated.

Stimulation of the periarterial nerves with single . square pulses of maximum or near-maximum duration (0.5 or 1 msec) and maximum strength produced a depolarization of the cell membrane lasting 0.5 to 1 secthe EJP (Fig. 1a and b). Marked facilitation of the EJPs occurred in response to repetitive periarterial nerve stimulation. With rates of stimulation of 2/sec or faster there was summation of EJPs because of incomplete repolarization of the preceding EJPs (Figs. 1 and 2). The delay between stimulus artefact and onset of the EJP could be as brief as 12 msec (Table 1, Fig. 1b), a result which indicates a rapid access of the transmitter to the receptors and their prompt activation by the transmitter. Rise times of the EJP varied not only between preparations but also within a series of EJPs produced by repetitive stimulation (Fig. 1a).

The nature of the link between depolarization and contraction remains to be established. An action potential initiated by an EJP is necessary for nerve stimulation to produce a contraction of a number of smooth muscles. With arterial muscle, however, the necessity of an action potential for a contraction is controversial^{1,8}. In the present experiments, no EJPs were seen to trigger an action potential, although previously they could be

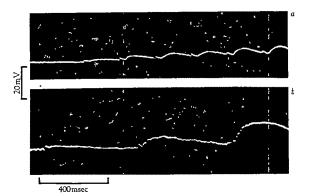

Fig. 1. Excitatory junction potentials to periarterial nerve stimulation recorded intracellularly from rabbit arterial muscle cells (arteries perfused with Krebs solution in vitro). a, The first side branch leaving the posterior mesenteric artery. Nerve stimulation at 5/sec with square pulses of 1/msec duration and 50 V. Maximum resting potential was 60 mV. b, Rabbit car artery. Nerve stimulation at 2/sec, 0.5 msec and 50 V. Maximum resting potential was 60 mV.

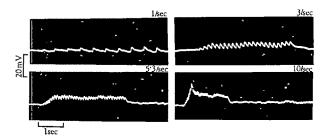

Fig. 2. Excitatory junction potentials to periarterial nerve stimulation at different stimulus frequencies. All records are from the same muscle cell in the first side branch of the rabbit posterior mesenteric artery. Repetitive nerve stimulation with pulses of 1 masc duration and 50 V.

Maximum resting potential was 60 mV.

demonstrated when guinea-pig mesenteric arteries with an intact circulation were used. Instead, high rates of stimulation produced a sustained depolarization which showed a peak before falling to a lower level of depolarization (Fig. 2). These rates of stimulation were sufficient to cause a marked contraction. The stimulus frequencycontraction curve for the mesenteric artery has a threshold of about 2/sec and reaches a maximum between 10 and 20 pulses/sec (Speden, unpublished).

The risk of damage to the small cells on insertion of the microelectrode necessitates caution in the interpretation of negative results. Insertion of an electrode into a cell was accompanied by an abrupt fall in potential to negative values of 49-69 mV, which were high for vascular muscle, and the potential could remain relatively stable at these values for 3-4 min. These signs of satisfactory penetration were consistent with observations that action potentials of up to 25 mV could readily be recorded from the spontaneously active anterior mesenteric vein of the rabbit. The failure to elicit action potentials in the arterial muscles may therefore be an outcome of the high and stable membrane potential in vitro compared with in vivo3,5. Removal of the arteries from their natural site and their perfusion at the low perfusion pressures used (15-35 mm of mercury) must greatly reduce the excitatory influences acting on the muscle. Consequently, the muscle may be expected to be less easily excited, a conclusion consistent with the smaller EJPs observed, with one exception (Fig. 1b), in vitro as compared with in vivo. The maximum size of EJPs recorded from all other cells in the ear artery varied from 3.6 to 5.8 mV.

The EJPs which were recorded from the outermost muscle cells in the wall of the artery were similar in shape to those reported for the guinea-pig vas deferens¹⁰⁻¹². The smaller amplitude of the EJPs, compared with those of the vas deferens, may have resulted from a lesser density of innervation, a smaller release of transmitter from an equally dense innervation, a more rapid removal of released transmitter or a lower sensitivity of the cells to transmitter.

Transmission of Excitation from the Parasympathetic Nerve to the Smooth Muscle

Transmission of excitation from the parasympathetic (cholinergic) nerves to the smooth muscle has been investigated on the colon of the rabbit^{1,2}. Bennett³ has described the excitatory junction potential in response to stimulation of the intramural nerves of the taenia There is, however, much less coli of the guinea-pig. information about parasympathetic neuromuscular transmission than there is about transmission from sympathetic nerve to smooth muscle^{4,5}. This seems to be because there is no suitable parasympathetic nerve-smooth muscle preparation like the hypogastric nerve-vas deferens of the guinea-pig. Most smooth muscle cells previously used have both excitatory and inhibitory innervation and when stimulated transmurally the excitatory response may be modified by the inhibitory one. A more suitable preparation was therefore very necessary

We have used longitudinal muscles from the upper oesophagus, as far as the crop, from the chicken. The preparations have the advantage of receiving only cholinergic excitatory innervation. Excitatory junction potentials can be elicited by stimulating the intramural The junction potentials are comparable with those in the vas deferens of the guinea-pig, except for the much longer delay between nerve stimulation and the

onset of the responses.

Strips from the longitudinal layer of the upper oesophagus were mounted in a sucrose-gap apparatus. A pair of electrodes for transmural stimulation were embedded in the vertical tube of the apparatus through which flowed Krebs solution, so that stimuli could be given across part of the strip 3 mm from the recording electrode. Changes in membrane potential were recorded with the tension during transmural stimulation with supramaximal single square pulses lasting 0.3 msec or less.

The resting potential of the muscle was 39-53 mV (mean, $47 \pm 2.5 \text{ mV}$; n=14). Some preparations discharged spontaneous action potentials, which varied in amplitude from less than 5 mV to 25 mV, and also in shape. The most frequently observed shape of discharge consisted of complex spikes, two or more spikes occurring before the repolarization of the preceding spike was complete. This probably results from an asynchronous spike discharge from a number of cells in contact with the recording electrode. The intervals between discharges also varied.

The preparations with little spontaneous activity permitted observation of the response to the transmural

stimulation. Single pulses at intervals of 5 sec (Fig. 1a) gave a depolarizing response which initiated an action potential, thus resulting in a contraction. Usually the action potential arose from a slow depolarization (Fig. 1b).

The responses to transmural stimulation seem to result from stimulation of postganglionic cholinergic nerves, for they are completely blocked by atropine (10-7 g/ml. or less) and tetrodotoxin $(5 \times 10^{-8} \text{ g/ml.})$, which abolishes excitability of nerve and striated muscle but does not affect that of smooth muscle^{8,9}, and they are unaffected by hexamethonium (10⁻⁴ g/ml.). This is also supported by the fact that the chronaxie of about 0.1 msec is incompatible with the direct stimulation of the smooth muscle.

The muscular layer of the oesophagus in some species contains both striated and smooth muscle, and so we used d-tubocuraring and flaxedil to see if skeletal muscle

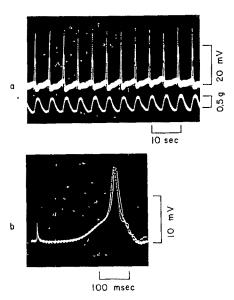

Fig. 1. Action potentials and contractions recorded from smooth muscle strips of the upper oesophagus of the chicken during stimulation of the intramural nerves. (a) Action potentials and contractions produced by stimuli with square pulses of 0·1 msec duration and 25 V at a frequency of 0·2/sec; (b) superimposed record, at faster speed than (a), of action potentials produced by five stimuli in another strip.

participated in the responses. The responses, however. were unchanged in the presence of these drugs in a concentration large enough to block the neuromuscular junction in skeletal muscles. Okamoto, Sugimura and Nonomura (personal communication) have also observed histologically that this part of the oesophagus in the chicken does not contain striated muscle. It is thus concluded that the slow depolarization in response to transmural stimulation is a junction potential of smooth muscle. The preparations, even after treatment with atropine, did not give a hyperpolarizing response, and therefore the preparations probably receive only the cholinergic excitatory innervation.

We could not record only junction potentials when the stimulus strength was gradually decreased with a constant pulse duration. A possible explanation for this result is that the depolarization in response to the stimulation reaches easily a critical level to fire a spike because of the lower membrane potential of the smooth muscle cells.

In Krebs solution containing more magnesium ions (10 mmolar), however, the spike generation of the smooth muscle cells was blocked, but the junction potentials persisted. The amplitude of depclarization of the junction

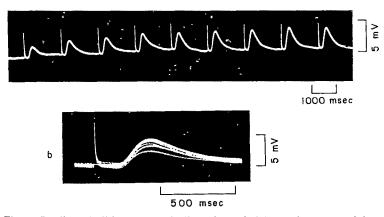

Fig. 2. Junction potentials in response to stimulation of the intramural nerves recorded from a smooth muscle strip of the upper oesophagus of the chicken in Krebs solution containing 10 mmolar magnesium ions. (a) Junction potentials produced by nine stimuli of 0.3 msec duration and 20 V at a frequency of 0.8/sec; (b) superimposed record, at faster speed, of junction potentials produced by five successive stimuli.

potentials increased with successive stimuli, and reached its maximum after several stimuli (Fig. 2, a and b). This facilitation occurred even when the interval between stimuli exceeded 1,000 msec. The junction potential took from 150 to 250 msec to reach its maximum height and it lasted from 700 to 950 msec. Sometimes the junction potential triggered a spike even in solutions containing high concentrations of magnesium ions.

The delay between nerve stimulation and the onset of the excitatory junction potential was from 90 to 160 msec (mean, 130 ± 22 msec; n = 15). This delay might be caused by conduction in the intramural post-ganglionic fibres and by transmission from the nerve to the smooth muscle.

In a few experiments, the stimulating electrodes were moved to various distances from the recording electrode to measure the conduction velocity of the intramural nerve fibres. Changes in the delay were observed which suggested that impulses might conduct more slowly in the intramural nerve fibres than in C fibres.

Effects of Presynaptic and Postsynaptic Inhibition on the Variability of the Monosynaptic Reflex

Successive monosynaptic reflexes evoked by essentially constant afferent volleys usually show considerable fluctuations in size1,2. It has been suggested1-3 that the chief cause of such variability would be background activity of interneurones impinging on to motoneurones. Monosynaptic transmission from afferent fibres to motoneurones may be controlled at the postsynaptic as well as the presynaptic level4, and so the question arises: which internuncial system, terminating either pre- or postsynaptically, is actually contributing to the mono-synaptic reflex fluctuations? For this reason we have compared the effects of afferent volleys leading to preand postsynaptic inhibition on fluctuations of the monosynaptic reflex.

Twenty-one cats were initially anaesthetized with ether and the spinal cord was transected at the first cervical segment, after which circulation in the head was occluded. All animals were immobilized with gallamine triethiodide ('Flaxedil') and maintained by artificial respiration. Monosynaptic reflexes were produced by graded stimulation, at a constant frequency (0.6-0.8 c.p.s.), of group I afferents of the medial and lateral gastrocnemius. The reflex responses were monophasically recorded from the central ends of the ipsilateral cut L7 or S1 ventral roots. The afferent volley was recorded monopolarly from the

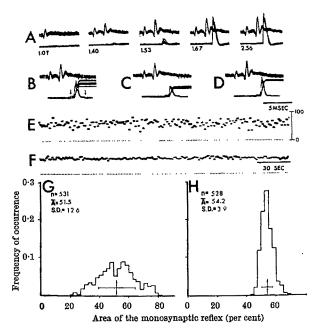

Fig. 1. A, Monosynaptic reflexes produced by graded stimulation of medial and lateral gastroenemius afferent nerves. Upper traces, afferent volleys recorded from the dorsal root entry zone. A subthreshold constant stimulus (1·12T) preceded the test shock by 2 msec to obtain a large reflex response. Lower traces, reflex discharges from the L7 ventral root. Strength of test shock given at the bottom. B, Control test responses produced by a constant stimulus (1·57T). Upper trace, afferent volley; lower trace, monosynaptic responses and its corresponding areas obtained with an integrator. The response superimposed on a small square wave (see arrows) showing the interval of integration. C, Same as B, but test response preceded 30 msec before by three shocks at 300 c.p.s. to the deep peroneal afferents (1·5T). The monosynaptic reflex is depressed and D shows the result of increasing the test stimulus (1·8T) to obtain the same mean response. Note the decrease of area fluctuations between B and D. E and F, Continuous records of the areas of B and D respectively, stimulating at 0·6 c.p.s. The height of the coarse dots above the baseline (fine dots) gives the area of each reflex. G, Histogram for 531 successive reflexes partly illustrated in B and E. Arrow points to mean area (A) and horizontal segment gives two standard deviations (S.D.). Area of maximum response set at 100. H, Histogram of 528 reflexes under deep peroneal inhibition as in D and F. Note mean area is within 5 per cent of that in G, but the S.D. is three times smaller.

dorsal root entry zone. An analogue computer was usually used to calculate continuously the average area of the group I afferent volley (Ai), average area (Ao) and variance (σ_0^2) of the monosynaptic reflex. The computation will be described elsewhere (see also ref. 5). Computer measurements were often verified by hand calculation and agreed within 15 per cent. The temperature of the exposed cord was kept at 37°-38° C with radiant heat.

The monosynaptic reflexes produced by stimulation, with increasing strengths, of group Ia afferents of gastro-cnemius are shown in Fig. 1A. Although the afferent volley was nearly constant, the area of the monosynaptic reflex showed considerable fluctuation (Fig. 1B). From a continuous run of 531 reflexes, partly illustrated in Fig. 1, B and E, the histogram G was prepared. The distribution of areas was approximately normal with a mean of 51.5 (maximal response set to 100) and a standard deviation of 12.6. The variation coefficient, that is, the ratio of standard deviation to mean response, was 0.245 for this control series.

The monosynaptic reflex was reduced to about 60 per cent of its original size when preceded 30 msec before by a conditioning volley 1.5T (1.5 times the threshold of the most excitable fibres) applied to the deep peroneal afferent fibres (Fig. 1C). In these conditions depression of the monosynaptic reflex would be essentially the result of presynaptic inhibition⁴. To compare variabilities for the same mean response the strength of the test stimulus was increased until the monosynaptic reflex regained its original size (Fig. 1D). With conditioning volleys from the deep peroneal nerve there was a striking reduction in fluctuations of the monosynaptic reflex (Fig. F1 and H). The standard deviation decreased to 3.9 and the variation coefficient to 0.072.

Fig. 2A, B and C shows the data obtained from the same animal where the action of pre- and postsynaptic inhibition was compared throughout the range of the monosynaptic reflex input-output curves. When the average area of the monosynaptic reflex (Ao) was increased (by increasing the afferent volley), the variance (σ_2^2) also increased up to a maximum and then declined (Fig. 2A, open squares and circles). The variation coefficient decreased monotonically as the mean monosynaptic reflex was increased (Fig. 2C).

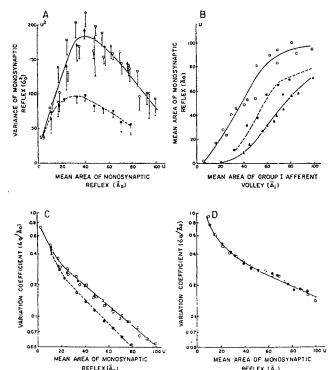

Fig. 2. A and B, Variance versus mean area and corresponding inputoutput curves for the monosynaptic reflex. Each point is the average
of the raw data obtained by point-plotting the computed values every
7-5 sec for 5 min at a fixed stimulus strength. Open circles, control
measurements without any inhibition. Closed circles, during presynaptic inhibition (three shocks to deep peroneal at 300 c.p.s., 1-35T,
35 mscc before test stimulus). Control and conditioned points were
obtained alternately. Closed triangles, during postsynaptic inhibition
(one shock to PL-FDHL, 1-31T, 2 msec before test stimulus). Open
squares are the corresponding control values. The vertical bars in A
give the standard deviation of the raw data obtained from the same
cat over a period of 4 h. C, Varlation coefficient versus mean area
curves constructed from the data shown in A. Stimulus frequency
0-8 c.p.s. D, Varlation coefficient versus mean area for another animal.
Open circles, control curve. Closed triangles, conditioned curve obtained when the test monosynaptic reflex, recorded from a small L7
ventral rootlet was preceded by a constant supramaximal pulse applied
10 msec earlier to the other part of the root. Note logarithmic scales
in the ordinates of C and D. In both experiments, monosynaptic
reflexes were produced by a single afferent volley to gastrocnemius.

When the test stimulus was preceded by a constant train (1.35T) applied to the deep peroneal afferents 35 msec earlier, so as to produce presynaptic inhibition, the input-output curve was displaced to the right (Fig. 2B, closed circles). In addition the variance curve was displaced below the control curve for most of the explored range (Fig. 2A, closed circles). This made the variation coefficient curve much steeper (Fig. 2C, closed circles). A similar reduction in variability was observed when the conditioning train was applied to the posterior bicepssemitendinosus (PBST, 1.2-2T) or to the sural (1.5-2T)afferent fibres, 30-50 msec before the test stimulus. The time course of reduction of variability closely resembled that of the depression of the monosynaptic reflex by pre-

synaptic inhibition4: onset at 5-10 msec, peak at 20-40 msec and a gradual decay up to 100 msec. Picrotoxin (1-2 mg/kg), which depresses presynaptic inhibition4, also reduced the effects of deep peroneal and PBST afferent volleys on the variability of the monosynaptic reflex.

Contrary to the actions produced by presynaptic inhibition, the variability curves remained essentially the same when an afferent volley to the plantaris flexor digitorum and the hallucis longus (PL-FDHL) was timed so as to reduce the monosynaptic reflex by postsynaptic inhibition^{4,6}. For example, in Fig. 2A, B and C the closed triangles show measurements obtained when the test stimulus was preceded, 2 msec before, by a single volley to Ia and Ib afferents (1.31T). Although the inputoutput curve was displaced to the right, indicating inhibition (Fig. 2B), the variance-output and variation coefficient—output curves remained unaffected (Fig. 2A and C). Similar negative results were obtained when the afferent volley was applied to the deep peroneal afferents $(1\cdot2-1\cdot5T, 2-5 \text{ msec earlier})$ or to a neighbouring ventral root, which also depresses the monosynaptic reflex by way of inhibitory synapses with motoneurones' (Fig. 2D).

The results show that the variability of the mono-synaptic reflex can be reduced by presynaptic inhibition but not by postsynaptic inhibition. This suggests that in the non-anaesthetized spinal cat the variability of the monosynaptic reflex is chiefly introduced at the presynaptic level. Intermittent activity along the paths leading to primary afferent depolarization (PAD)4 would produce fluctuations of the membrane potential of the $\tilde{\mathbf{I}}a$ nerve terminals. This would in turn affect the amount of transmitter substance released by each presynaptic terminals or the number of fine Ia terminals invaded by the presynaptic impulse. Variability reduction produced by the presynaptic conditioning volley can be explained by assuming that the potential fluctuations of the Ia terminals are reduced either at the terminal itself or along the paths leading to PAD. In the first case, PAD produced by the conditioning volley could reduce the potential fluctuations by decreasing the input resistance of the terminals. In the second case, the activity along the paths leading to PAD would be decreased by refractoriness after the conditioning volley or by active inhibition. Evidence for the latter is given by the reduction in variability produced by the Sural low-threshold afferents which are known to inhibit transmission along the paths leading to depolarization of the Ia fibres10. The role of variability reduction by presynaptic inhibition is still uncertain because we do not know whether the same effect would be obtained by natural, asynchronous activation of peripheral receptors¹¹.

Spontaneous Activity recorded from the Central Cut End of the Carotid Sinus Nerve of the Cat

THE receptor in the carotid body for changes in blood gas tensions has for many years been assumed to be the glomus cell^{1,2} or Type I cell³. Lever, Lewis and Boyd⁴ showed by electron microscopy that the nerve endings adjacent to these cells contain microvesicles, of the same dimension as synaptic vesicles, and small mitochondria, and this observation was confirmed by Biscoe and Stehbens^{5,6}, who described the structure of the endings in greater detail and showed that they are similar to those of an efferent type in other parts of the nervous system, and share a dense junctional region with the Type I cell membrane. Biscoe and Stehbens's later found that the endings degenerated after the carotid sinus nerve was cut, and it seemed probable, in accordance with the evidence of De Castro^{1,2}, that they were afferent nerve endings. It is also possible, however, that such endings arise from efferent nerve fibres coursing in the carotid sinus nerve to the carotid body. The purpose of the present experiments was to seek evidence for such efferent fibres.

Six cats were used in the experiments. anaesthetized with 'Dial-Urethane' (Ciba), 0.6 ml./kg given intraperitoneally, a tracheal cannula was inserted, and the carotid sinus region was exposed on the medial The end-tidal carbon dioxide was continuously monitored with an infrared analyser (Beckman LBI). A femoral artery was cannulated to record arterial pressure with a Statham strain gauge, and arterial blood samples were taken through this cannula for blood gas analyses. In some experiments the femoral artery and vein on the opposite side were also cannulated and were joined through a cuvette which housed a Beckman oxygen macro-electrode to monitor arterial oxygen tension (paO₂). The variables were monitored continuously and recorded on a polygraph, in parallel with the output of a ratemeter which was used to monitor the discharge rate of nerve impulses. The carotid sinus nerve was sectioned close to the carotid body, and nerve impulses in fine strands (5-25μ diameter) from the central cut end of the sinus nerve were recorded through platinum wire electrodes and displayed on an oscilloscope. They were also photographed on moving film from another oscilloscope. In some experiments, gallamine triethiodide was administered intravenously, and the cats were artificially ventilated.

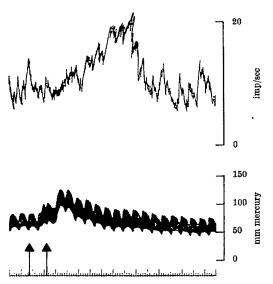

Fig. 2. Effects of adrenaline on the discharge of fibres recorded from the central cut end of the sinus nerve. The fibres were of the type that remain discharging after the ipsilateral sympathetic nerve is sectioned pre-ganglionically (see Fig. 1C). The upper tracing represents the output of the ratemeter; the lower tracing is arterial blood pressure. At the first arrow, adrenaline (20 µg/kg) was given intravenously, and at the second arrow it was washed in. The time scale is in seconds.

In all preparations two types of spontaneous activity were found in the central end of the sinus nerve. The first, and the easiest to record, often showed a pattern of discharge in phase with respiration, and in some cases a cardiac rhythm was also apparent. The nerve activity increased when the arterial blood pressure fell, decreased when the arterial pressure rose after the intravascular administration of adrenaline, and it was abolished by section of either the pre-ganglionic cervical sympathetic nerve or the post-ganglionic internal carotid branches of the superior cervical ganglion. Fig. 1 shows one example of this; in A is the resting discharge in a multi-fibre strand and in B, at the arrow, the ipsilateral pre-ganglionic sympathetic nerve was cut, and all activity, except for a single action potential shown in C, was abolished. This potential could be identified on the original film record before the nerve was cut, and it showed a delayed increase in rate of discharge after the intravenous injection of adrenaline, at a time when the activity of the other nerve potentials was depressed. Finally, stimulation of the

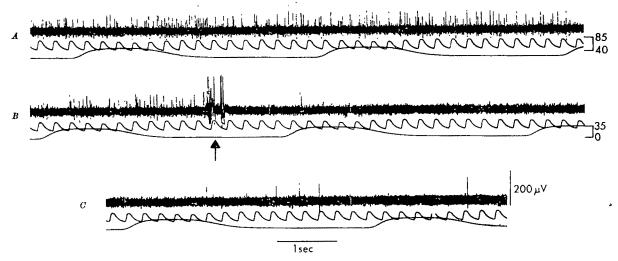

Fig. 1. Continuous record of nerve action potentials recorded from the central cut end of the sinus nerve. In each record the upper tracing is the nerve potential, the middle tracing is arterial blood pressure, and the lower tracing is end-tidal carbon dioxide. Calibration in A represents blood pressure (mm of mercury), in B it represents end-tidal carbon dioxide (mm of mercury), and in C it represents action potential amplitude. Calibrations and time scale apply to all records. A, Resting discharge in a multi-fibre strand. B, The pre-ganglionic cervical sympathetic nerve was cut at the point marked by the arrow, where there is also a movement artefact. C shows a single nerve potential which remains after nerve section. The arterial pressure and end-tidal carbon dioxide were unchanged throughout.

pre-ganglionic cervical sympathetic nerve on the recording side evoked a compound action potential in the central end of the sinus nerve.

The second type of activity was more difficult to find and the action potentials as recorded by this method were generally smaller than those of the first type in any one preparation. The activity did not seem to occur in bursts synchronized with either respiration or the heart beat. In addition, it was not abolished by cutting the pre-ganglionic cervical sympathetic nerve ipsilaterally, nor did stimulation of the cervical sympathetic nerve evoke a compound action potential in strands which contained this type of nerve activity. The rate of discharge of fibres of this type increased when the paO2 was lowered from 250 to 50 mm of mercury, or when the arterial carbon dioxide and hydrogen ion concentrations were raised by altering the end-tidal carbon dioxide in the range 20 to 120 mm of mercury. This increase in discharge was roughly linear with increasing carbon dioxide and approximately hyperbolic with decreasing oxygen tension. The response curves were not as smooth as those for the carotid body chemoreceptors, however, because the discharge in the sinus efferents tends to occur irregularly in bursts. These may be seen in the ratemeter record of Fig. 2. The changes in discharge rate with alterations in blood gas tensions occurred even after the contralateral sinus nerve, both aortic nerves, both vagus nerves and both pre-ganglionic cervical sympathetic nerves were cut. The rate of discharge also increased when the arterial pressure was raised by the intravascular injection of adrenaline, although there was usually a long latent period before this rise in activity. Sometimes the rate did not increase until the arterial pressure had started to fall, as long as 20-30 sec after the injection (Fig. 2). The increase in rate of response to adrenaline persisted even after the contralateral sinus nerve, both vagus nerves and both pre-ganglionic cervical sympathetic nerves had

We conclude from these experiments that the first type of activity is sympathetic in origin, and that the second type arises intracranially, perhaps from neurones which are directly excited by adrenaline. In studies of the central connexions of the sinus nerve, such neurones would be excited antidromically by electrical stimulation of the sinus nerve, and their identification would be of great interest.

The destination of these two groups of nerve fibres is unknown. With reference to the first group, it has previously been shown that nerve fibres from the superior cervical ganglion terminate adjacent to the blood vessels in the carotid body^{8,10}, but no signs of degeneration of endings in this position were seen after the sinus nerve had been cut. If the fibres of the second group terminate in the carotid body, they may be efferent to the glomus or Type I cells. Such a possibility can be substantiated only by degeneration studies with the electron microscope. If these fibres do provide the source of the nerve endings on the Type I cells, however, it is legitimate to ask, where are the chemoreceptor nerve endings?

Effect of Arterial Oxygen on Mammalian Brain Oxygen Tension

EXPOSURE to one atmosphere of oxygen has been found to cause changes similar to retrolental fibroplasia in the cerebral cortex of newborn mice1, and exposure to oxygen at pressure greater than 2.5 atm. can often cause a grand mal type of convulsion in mature mammals2. The nature of such oxygen toxicity is unknown, and studies of the effect of this gas on various tissues have been hampered by the inability to monitor directly the oxygen tension in a tissue with accuracy.

One of the most useful techniques so far used to estimate the tissue oxygen tension (pO₂) makes use of a metal polarographic electrode³. Such an electrode, however, tends to consume oxygen faster than tissue diffusion can replace it; the bare metal may react with many of the substances present in biological systems resulting in artefactual pO2 values and these electrodes are usually too large for intracellular measurements. These difficulties can be overcome by using electrodes covered by a polyethylene membrane, which is impermeable to most biologically important molecules other than oxygen4; and by using the intermittent pulse method of Naylor and Evans^{5,6} which greatly reduces the amount of oxygen consumed.

Intermittent polarographic membrane electrodes (IPM electrodes) were used for oxygen determinations in the cerebral cortex of four healthy rhesus monkeys. The rhesus monkeys (weighing 2·4-3·4 kg) were anaesthetized with 30 mg/kg of 'Nembutal' and then an endotracheal tube was inserted. This tube was attached to a respirator pump which was run at 10 strokes/min (100 ml./stroke). Normal ventilations reported for non-anaesthetized monkeys are 1,410 and 863 ml./m in 3.08 and 2.68 kg monkeys, respectively7. Body temperature was maintained by a thermostated pad and a Charlton flexible pO2 microelectrode was inserted into one of the femoral arteries8. The other femoral artery was catheterized for continuous blood pressure measurements.

The scalp was reflected from the right parietal area and a hole 1 cm in diameter was made in the skull by trephination. The dura was dissected away and an IPM electrode (tip diameter 1 mm) was gently positioned at a depth of about 1 mm below the surface in the grey matter of the frontal lobe, 1 cm to the right of the midline and 1 cm anterior to the sulcus centralis. The IPM electrode was supported in a pivoting counterbalanced clamp allowing it to move with the pulsations of the brain. Although the IPM electrode was placed in relatively avascular sites in the tissue, its surface area was such that the readings obtained must have been representative of average tissue oxygen tension. Only when the electrode was located directly over an arteriole were larger values obtained. Furthermore, the size of the tip was such that there was some damage to tissue during its insertion.

The IPM electrodes used had platinum cathodes 0.003 in. in diameter which were polarized at -0.7 V every 1.6 sec for 30 msec to assure minimal oxygen consumption. They had an accuracy of ±5 mm of mercury. Intermittent arterial samples were taken in heparinized

- * 100 per cent or 95 per cent oxygen and 5 per cent carbon dioxide gas mixture.
- † Each value given represents the mean of at least five readings.
- ‡ This animal had an average arterial pCO₂ 22 mm of mercury greater than the other animals in this study.

syringes for determination of the partial pressure of carbon dioxide (pCO₂) using a pCO₂ electrode. All electrodes were calibrated using solutions tonometered with analysed gas mixtures accurate to $\pm\,0.03$ per cent.

Each monkey was monitored until it reached a steady state on room air (no change in arterial gas tension for 5 min or longer), then the gas intake was switched to a high oxygen atmosphere at ambient pressure until a steady state was again achieved. Finally, the animal was returned to room air. This gas mixture cycle was usually repeated at least three times with 100 per cent oxygen and at least once with 95 per cent oxygen and 5 per cent carbon dioxide. The IPM electrode was often moved to an adjacent site for each cycle. These experiments usually lasted 2–3 h.

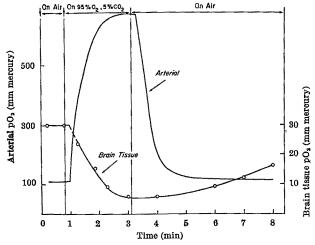

Fig. 1. Oxygen tension in monkey brain during changes in arterial oxygen tension. This study represents one of five similar cycles of events during 2 h. The continuous curve represents pO_n in femoral artery, redrawn from continuous recordings. The discontinuous dotted line represents brain pO_a . Each point represents the mean of at least five readings. The time-course was not corrected for response rates of the electrodes which were: arterial pO_a electrodes, 21 sec to 95 per cent full scale; brain IPM electrode, 6 sec to 95 per cent full scale.

Table 1 shows both the range of and the average pO₂ in the arterial blood and in eighteen areas in the cortical grey matter: five adjacent areas were monitored in the cerebral cortex in each of three monkeys and three adjacent areas in the fourth. The range of pO₂ observed in each monkey brain was rather large; however, in any particular area monitored the pO₂ was relatively constant during the steady state while breathing either air or an atmosphere rich in oxygen. The average arterial pO₂ was 104 mm of mercury, while the average brain pO₂ was 31 mm of mercury on room air. When these monkeys were switched to 100 per cent oxygen the average arterial pO₂ rose to 582 mm of mercury, while the average brain pO₂ dropped to 18 mm of mercury. Blood pCO₂ remained relatively constant at about 20 mm of mercury on air and 100 per cent oxygen in three monkeys and 42 mm of

mercury in the last monkey. (A pCO2 of 20 mm of mercury seems to be low when compared with normal pCO2s found in man (about 40 mm of mercury); however, a mean arterial pCO₂ of 28 mm of mercury (range 34-20 mm) was obtained from samples taken anaerobically from a catheter in the femoral artery of five non-anaesthetized rhesus monkeys in restraining chairs. taken to prevent excitement of the monkeys and subsequent hyperventilation during these studies.) A similar result was obtained with 5 per cent carbon dioxide and 95 per cent oxygen, with an increased arterial pCO₂ (about 36 mm of mercury) shown in Fig. 1. This decrease in brain pO2, in response to increased arterial oxygen, occurred in seventeen of the eighteen cycles monitored. In one cycle, no change in brain oxygen tension was observed. There was no significant change in either brain temperature or arterial blood pressure during the course of these experiments.

We have carried out similar experiments with rats which suggest that they may have a less well developed defence mechanism towards oxygen toxicity than the monkey, and the observation of Bean and Siegfried that the rats subjected to brief repeated exposures to oxygen at high pressures often became permanently paralysed supports this speculation. In our experiments, however, the rise in the average brain pO₂ from 50 mm to 88 mm of mercury when the rats were taken from room air to 100 per cent oxygen may be the result of experimental artefacts caused by an inability to control the rat's arterial gas tension.

A depressed cortical oxygen tension, observed in the monkey cortex in the presence of an elevated arterial pO2 and constant arterial carbon dioxide tension, could be caused by varying cortical tissue diffusion parameters, a change in capillary permeability, arteriovenous shunts, an increased cortical metabolic rate and/or a decreased The first two possibilities have not been amenable to extensive experimental examination. The studies which have been performed on rates of oxygen exchange between blood and tissues have not, however, revealed such changes10. The third possibility is contradicted by a number of anatomical studies which have failed to demonstrate the existence of arteriovenous shunts in the normal brain11,12. As for an increased metabolic rate, normal young men¹³ showed no change in cerebral oxygen consumption during inhalation of high mixtures containing 85-100 per cent oxygen. In the same study, however, a 13 per cent decrease in mean cerebral blood flow (from 52 to 45 ml./100 g/min) was noted with a moderate increase in cerebrovascular resistance. If the decrease in cortical tissue pO2 was the result of a vasoconstrictive effect of high arterial oxygen tension, it is surprising that the 5 per cent carbon dioxide in the inspired air is unable to overcome this effect, because carbon dioxide is one of the most powerful vasodilators in the central nervous system.

Whether the decrease of cortical tissue oxygen tension observed in the monkey in these experiments is caused by a regional vasoconstriction or some other mechanisms, such as increased cortical metabolic rate or a change in diffusion of oxygen, could not be ascertained in these experiments.

Effect of Anabolic Steroids on Plasma Glycoproteins

WE have previously reported an increase in α_2 - and β -globulins and an increase in β -lipoprotein after administration of the anabolic steroid, 17-ethyl-19-nortestosterone (norethandrolone) (Fig. 1A) to human subjects¹, and our subsequent work (unpublished) disclosed that this increase in serum protein fractions is associated with increases in protein bound carbohydrates (Fig. 2). We have recently had the opportunity to study the effects of an anabolic steroid with a unique chemical configuration, oxandrolone (Fig. 1B), in eleven patients with disorders of lipid metabolism. This compound was found to cause a marked increase in α_2 -globulin (P < 0.001) but no change in β-globulin. Associated with this, there was a highly significant increase in α_2 -glycoprotein (P < 0.01, > 0.001) in all the patients studied (Fig. 3). The increases in α_2 -globulin and glycoprotein were definitive in all the eleven patients 5 weeks after the start of oxandrolone therapy. Thus it seems that both these anabolic steroids significantly enhance the concentrations of plasma glycoprotein.

Testosterone may lower the fasting blood sugar and reduce glycosuria and insulin requirements in some diabetic patients2, and anabolic steroids have recently been found to have a similar action in the diabetic state and

Fig. 1. Structural formulae for norethandrolone (A) and exandrolone

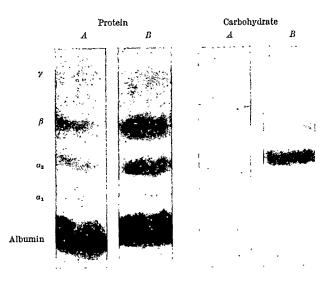

Fig. 2. Serum proteins and glycoproteins before (A) and during (B) administration of norethandrolone. Note the increases in α_2 - and β -globulin and glycoprotein during administration of the steroid. The electrophoretic strips were stained for protein with naphthalene black 12B 200 (ref. 5) and for carbohydrate by the periodic acid-Schiff reaction (ref. 6).

also to restore reactivity in the patient who is resistant to insulin^{3,4}. In view of the increased glycoprotein synthesis and the improvement in diabetes with these anabolic steroids, hypotheses correlating the two effects may be put forward. It is possible that these compounds divert glucose to glycoprotein synthesis by: (a) enhancement of the hexokinase pathway in the liver which is not dependent on insulin, resulting in shunting glucose to this intermediate metabolic pathway; (b) a primary enzyme induction of glycoprotein synthesis; or (c) inhibition of gluconeogenesis, diverting amino-acids from synthesis of carbohydrate precursors to glycoprotein. One or a combination of these mechanisms could result both in an increase in glycoproteins and an improvement in carbohydrate metabolism in the diabetic. It will be necessary to study further the effect of this increase in plasma glycoprotein on basement membrane or on small blood vessel disease of the diabetic.

This work was supported in part by a grant from G. D. Searle and Company. We thank Drs Howard S. Schwartz and Herbert Ross for helpful discussion, and Dr Robert Daniel, of G. D. Searle and Company, for supplies of oxandrolone.

BIOLOGY

Possible New Approach to the Chemical Control of Plant Feeding Insects

THE chemical control of insects has been hampered by the widespread development of strains which are resistant to Resistance mechanisms often involve detoxication processes2, and many detoxication mechanisms in resistant strains have two features in common. First, they are not peculiar to the resistant insects. Susceptible strains often degrade the insecticide by similar metabolic pathways, but much less extensively, and the biochemical novelty which confers resistance is thus often quantitative rather than qualitative. Moreover, comparable detoxication pathways establish the natural tolerance of species which lack resistant strains2,3. Second, resistance involving detoxication can usually be overcome or reduced if the insecticide is applied with a non-toxic dose of synergist². The synergists appear to inhibit enzymes involved in detoxication. The best known are methylenedioxyphenyl compounds such as piperonyl butoxide and sesamex which reduce the resistance of insects to DDT^{2,4,5}, pyrethrins⁶, organophosphates⁵, carbamates⁷ and dieldrin⁸, and the tolerance of susceptible strains to these and other insecticides, including several derived from plants, as discussed in refs. 9 and 10.

Whereas resistance to man made insecticides has evolved in a few decades, relationships between insects and plants have evolved since long before the evolution of man himself. Plants have evolved minor constituents which have been called secondary plant substances and include glucosides, alkaloids, etc., which are often specific to particular plant taxons. The function of many of these compounds is unknown, but Fraenkel considered that the host-specificity of plant-feeding insects was based on their presence or absence¹¹. This interpretation may not always be applicable 12; nevertheless, it is obvious that a successful pest must be able to tolerate any substance present in its host plant. Some secondary plant substances are highly active pharmacological substances, or are mammalicidal. Some—for example, pyrethrum and nicotine—are insecticidal¹³, and it has been suggested that others -for example, cyanogenic glucosides14, alkaloids15 and mustard oils16-protect plants from the attack of insects or other pathogens.

Although investigations of plant-host relationships have involved studies of the repellency, attractiveness or toxicity of secondary plant substances, little seems to be known about the mechanisms by which potentially toxic substances in the normal host plant are tolerated. seven species of insect feeding on tobacco plants, however, three are known to detoxify nicotine 17.

It seems probable that some other plant feeding insects tolerate poisonous substances in their plant hosts because they have evolved detoxification mechanisms. If so, it should be possible to interfere with these mechanisms by

the application of a synergist. Such compounds would represent a new type of chemical control agent which need not be toxic because they would act by enhancing the effectiveness of naturally occurring plant protectant substances. They would be unlikely to affect predatory and pollinating insects and would probably be most useful in plants containing potentially toxic substances chiefly in those parts not eaten by man-for example, solanin in the leaves of potato plants. Such compounds might also be effective against other plant pathogens such as fungi.

In view of the long period during which the interrelationships between plants and insects have evolved, it is possible that some secondary plant substances have evolved as synergists to enhance the action of other naturally occurring protective substances. In this respect, it is of interest that the synergistic properties of the methylenedioxyphenyl compounds were discovered when sesamin was found to be the active principle responsible for the synergism of pyrethrins by sesame oil. More than three hundred compounds containing the methylenedioxyphenyl group, including alkaloids, flavones, benzophenones and lignan compounds, are known to occur naturally in plants18, and several besides sesamin have been shown to synergiza insecticides 19-21.

Nature's Time-scale: Degenerative Disease in Man

McCormick¹ recently formulated the following hypothesis: "All naturally occurring phenomena proceed according to exponential functions of time and each process in Nature conforms to its own unique time-scale". He finds that the empirical equation

$$Y = \exp(-kt^{-c}) \tag{1}$$

describes a variety of different processes and that the values of the constants k and c are characteristic of the particular process. Fremlin² points out that for any natural phenomenon the value of t must be subjected to an arbitrary cut-off at some finite value and that this kind of law is usually restricted to processes which occur under controlled conditions. In replying to Fremlin's² objection that equation (1) is incapable of describing periodic phenomena, McCormick³ concedes that in such situations a series of exponential growth and decay functions are needed, each valid within certain limits of t.

The age distribution of disease in man is of considerable interest in the context of this discussion. Clinicians have long been aware that the sex and age patterns of many diseases are more or less invariant both with respect to secular time and geography. It has been found4-10 that the sex-specific and age-specific prevalence, P, of many diseases of either autoimmune or unknown (but possibly autoimmune) aetiology can be described, often with impressive accuracy, by the following general equation¹¹

$$P = S\{1 - \exp(-kt^r)\}^n$$
 (2)

and that sex-specific and age-specific initiation rates (dP/dt) are often remarkably consistent with the differentiated form of the equation

 $dP/dt = nrkSt^{(r-1)} \exp(-kt^r) \{1 - \exp(-kt^r)\}^{(n-1)}$ where S is the proportion of the population (specific for sex where necessary) predisposed to the disease at birth, kis a constant from birth (or earlier) to all t of interest and t is age, corrected for latent period—the average interval between the initiation of the disease process and the onset of symptoms or signs. For most diseases4-11, it is sufficiently accurate to measure t from birth; r is a positive integer and $n \ge 1$. When r is unity, equations (2) and (3) reduce to the homogeneous birth or Yule process, and when n is unity, they reduce to a restricted form of the Weibull renewal process. For the great majority of diseases I have investigated $^{4-10}$ in this way, either n or r are equal to unity. For any specific disease conforming to (2) or (3) or both, the value of k is either the same in the two sexes or it is twice as high in XX females as in similarly predisposed XY males⁴⁻¹⁰. I have not yet encountered any clear-cut violation of this rule.

Equations (2) and (3) are derived from a simple biological model4-11 in which Burnet's12-14 "forbidden-clone" theory of disturbed-tolerance autoimmunity is combined with Burwell's15 concept that growth is regulated by lymphoid elements. In this unified view, the stochastic equations describe the probability of occurrence of spontaneous gene mutations in central, growth-control stem cells. These random events are supposed to initiate the growth of either one or n phenotypically distinctive and independent forbidden-clones, which synthesize cellular or humoral autoantibodies. At the end of the latent period, the attack of the autoantibodies on target tissue bearing complementary antigenic determinants results in the symptoms with or without signs of disease. Burnet's forbidden-clone concept12-14 explains how one, or a few, spontaneous somatic gene mutations can give rise to a disease in which numerous cells, in many anatomical situations, are simultaneously affected.

If there are at least n sets of cells at mutational risk, and if each set contains L cells, then when r = 1, k is defined as Lm. Here m is the average number of pathogenic mutations, per cell at risk, per unit time. When $r \ge 2$, k is defined as $Lm_1 \cdot m_2 \cdot ... \cdot m_r$. Equations (2) and (3) require, among other things⁴⁻¹¹, that m_1t , m_2t , ... etc. should be appreciably less than unity at all t of interest. When $k_F = 2k_M$, it is suggested that the mutation of an X-linked gene is implicated4-11.

If the spontaneous mutation of a specific gene in a specific set of stem cells is regarded as the elementary process in the initiation of many diseases in man, then this process is described by the familiar equations

$$dL = - mL dt (4)$$

$$L = L_0 e^{-mt} (5$$

Because m appears to be independent both of postnatal age and ordinary environments4-10, the mutational event may involve a unimolecular reaction process. Novick and Szilard¹⁶ studied the spontaneous mutation to resistance to bacteriophage T5 in E. coli (strain B/1) and they found, somewhat unexpectedly, that their results were consistent with a unimolecular reaction mechanism. The mutation rate m at 37° C, which was independent of the (controlled) generation time of bacteria, was found¹⁶ to be 1.1×10^{-4} yr⁻¹. I estimate that the value of m in man is

typically 10^{-3} yr⁻¹, although wide differences between one locus and another should be anticipated.

The parallel between the form of "biological decay" described by (4) and (5) and the law of radioactive decay is exact and, viewed in this way, many idiopathic human diseases may be said to exemplify McCormick's hypothesis (in its non-mathematical presentation). On the other hand, if the initiation of the disease itself is regarded as the basic process, then complications in the mathematical form of the age-distributions arise (when n and/or $r \ge 2$) because many diseases would appear to be initiated by multiple random events. A different kind of complication, analogous to one of those mentioned by Fremlin2, will manifest itself when, for example, S is a changing function of time. Nevertheless, it is intriguing to find that the age patterns of so many diseases in man should conform to such simple time scales.

Relationship of Sexual Receptivity to Menstrual Cycles in Adult Rhesus Monkeys

THE control of sexual reproduction in female rhesus monkeys involves not only an internal secretory rhythm, but also behavioural responses which must be in concert for the successful union of gametes. Grooming and mounting behaviour has been shown recently to be related to stages of the menstrual cycle1, and presentation to the male has been shown to relate to ovulation². The purpose of this study was to determine the extent to which receptivity of female monkeys to cannulation of the vaginal canal varies with the stages of the menstrual cycle in both brain lesioned and intact animals.

The female rhesus monkeys used had become accustomed to vaginal smear and cannulation procedures, and included a bilaterally temporal lobectomized animal. two which had sustained bilateral amygdalectomy and two animals with frontal lobe lesions. The animals were studied in two periods: the first period was during June-July 1966, in the presumed non-fertile season during which twenty menstrual cycles were recorded, two of which proved ovulatory; the second period was during October-November 1966, the presumed fertile season.

Physiological changes in the female reproductive tract were simultaneously gauged by assessment of vaginal smears taken daily by a procedure previously described. Ovulatory menstrual cycles were established by direct visualization of the ovaries during laparotomy. The animals were lavaged daily to recover all exfoliate materials available from the vaginal tract (mostly epithelial cells). This material sedimented out in 24 h when the

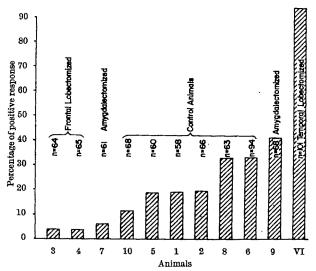

Fig. 1. Positive vaginal responses on cannulation in adult rhesus monkeys. n, No. of units of trials.

quantity was measured, thus permitting a determination of the vaginal exfoliation rate (VER), that is, c.c. of cells/24 h.

In the test procedure, the glass cannula was a blunt-ended eyedropper which was inserted and partially withdrawn in a penile-like action. One unit of trial, performed daily, consisted of up to twelve pulsatile movements followed by complete withdrawal repeated seven to ten times. The attempts of the animals to escape handling, or their co-operation, were tested by timing the interval they remained stationary after completion of the cannulations—"completion delay timings". This test was alternated with a procedure of counting the number of withdrawals from presentation made by the animals during periods of 30 sec taken at random during the cannulation trials.

Often during cannulation a tightening of the vaginal tract on the cannula occurred, which led to an airtight seal of the cannula in the vagina. When this occurred, it was scored as a positive vaginal response. Each animal was tested for this condition of muscular contraction and/or vasocongestion daily during and after cannula trials. Although the animals by and large did not interfere with the cannulations, there were two exceptions. On withdrawal of the cannula, one animal (VI) twisted back on the investigator and attempted—with a number of successes—to nip the hand of the investigator without

breaking the skin. She readily presented again after turning, and cannulation could be continued. A second animal (IX) manually sought out the cannula and the hand of the investigator without interrupting cannulation.

In control animals, there were positive vaginal responses in 11-33 per cent of the tests (Fig. 1). These occurred least in the frontal lobectomized animals, while one temporal lobectomized animal responded in 94 per cent of the trials, an extreme variation. The results in two amygdalectomized animals differed from one another, and further observations are necessary to see whether these results differ significantly from those from control animals.

In relation to the menstrual cycle, the test was usually sporadically positive in the intact animals and, when it could be related to stages of the menstrual cycle, it often occurred during the premenstruum (Fig. 2). In some instances, this response, as well as increased co-operativeness as judged by interval timings, could be related to the period of probable ovulation.

In Fig. 2, behavioural changes during both an ovular (July) and anovular (October-November) menstrual cycle have been correlated with daily vaginal exfoliation rates. The period of marked oestrogen effect in vaginal smears which occurred on the twelfth to fifteenth day in the July menstrual cycle is not indicated in Fig. 2. This period of probable ovulation corresponded to the period of marked proclivity on the part of the animal for the test procedure. While at other times in the menstrual cycle the period in which the animal waited for cannulation averaged 36.5 sec, during this period waitings were approximately six times more protracted, averaging 5 min 18 sec. Vaginal responses were positive on 3 days of this 4 day period.

During the anovular cycle no increased behavioural receptivity during the fertile period occurred; instead, the animal maintained presentation with the least number of postural changes in the premenstruum; in this period positive vaginal responses also occurred. This was a general finding in the anovular menstrual cycles of control animals.

Considering the animals as a whole, the results do not show any conclusive differences between the two periods of study. While four animals ovulated in the autumn, the seasonal variation differences which occurred in these four animals were believed to reflect differences in endocrine status.

While the test procedure used in this study can only be said to simulate male sexual activity, it has an advantage in that the response was measured from a constant, standardized stimulus.

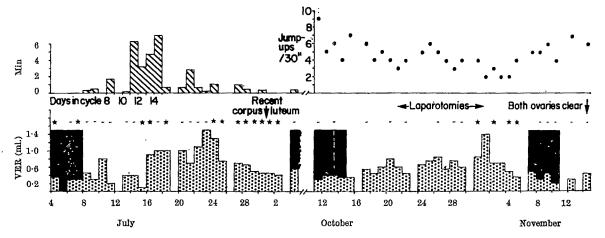

Fig. 2. Tests of sexual receptivity (♠) and vaginal responses (*) in relation to ovulation and stages of the menstrual cycle, together with vaginal exfoliation rates in rhesus monkey VI. Black bars denote menstrual bleeding.

Field studies4 indicate that the copulative behaviour of rhesus monkeys in the wild is more apt to occur in a 9 day period, presumably during the intermenstruum, and may not necessarily occur as an oestrous type of behaviour. Neither presenting—an invitational type of behaviour -nor mounting (including willingness to be mounted) are specific of oestrous behaviour. In the view of Carpenter⁴, the most discretely specific reaction of oestrous behaviour in the wild is when a female accepts a series of mountings with intromission.

The purpose of this study has been to explore this capacity for repeated intromission within a short interval of time, and the number of test trials were meant to induce a degree of satiation. If there was an oestrous type of receptivity, we measured how steadfastly the animals remained in the presentation position (completion delay and withdrawal timings) or persisted in the copulative

The vaginal muscular and/or vasocongestion test proved to be discriminative of the animal presumed to be hypersexuals, and permitted ranking of the less responsive animals. The condition of positive vaginal response could also be shown to occur during the probable period of ovulation, although the test did not prove specific for this period.

The finding of a premenstrual increase in vaginal response was unexpected because mounting and presentation behaviour at this time was not observed by Michael¹ or by Ball and Hartman². In the human, an increase in sexual desire in this period has been described6,7, as well as contractility or vasocongestion of the external third of the human vaginal tracts.

These present observations indicate that sexual excitability, as judged by vaginal contraction and/or vasocongestion, and receptivity, and also by completion delay timings, typically increases at the probable period of ovulation, and also occurs at other times during the menstrual cycle. This is consistent with what is known, namely, that female primates differ from lower animals in accepting the male in copulation throughout the menstrual cycle instead of for only a short period of time at ovulation.

Numerical Homology

THERE have recently been many objections to the orthodox definitions of biological homology in terms of common ancestry on the grounds that such definitions are circular¹⁻⁴. Parts of two organisms are defined as homologous if they are represented by a single part in a common ancestor. But homology itself is invoked in making this identification of parts of organisms with a part in a common ancestor. Various authors have advocated a return to Owen's criterion of homology-"the correspondency of a part or organ, determined by its relative position and connexions, with a part or organ in a different animal".

Jardine has formulated a logical model for correspondence of parts of things with respect to a set of relations along lines suggested by Woodger³, and from it has derived a general method for finding such correspondences.

A computer programme based on this method for finding biological homologies has been written. The first stage in the computing of biological homologies is the selection of a set of spatial relations and of a set of parts from each organism. The spatial relations holding between each pair of parts in each organism are then tabulated in matrix form, these being the data for the programme. The programme finds the largest correspondence or correspondences between some or all of the parts selected from each organism in which the spatial relations between parts are preserved. Thus if "anterior to" is one of the relations selected and x is anterior to y in one of the organisms, any parts p and q from another organism found to correspond to x and y, respectively, must be such that p is anterior to q. A symbol for "undecidable" in a given relation may be included in the data, an undecidable relation being allowed to map onto the relation or its converse. The programme has an option allowing for two or more parts to be considered together as a single part, and in this case it may find solutions in which a part in one organism corresponds to an aggregation of several parts in another. Another option allows for partial solutions to be fed in with the data in cases where at least some of the homologies of parts are not in dispute; this may save computer time.

The programme has been used in the study of the homologies of the bones of a variety of vertebrate skulls. For a number of simple cases it has been shown to yield satisfactory results. For example, the correct homology between the bones of human, cat, rat and dog skulls was found using the relations "anterior to", "dorsal to" and 'distal to". The success of the method in these simple cases suggests that it may be used in more complex cases

which involve large numbers of parts where the recognition of homologies by eye is difficult.

The homologies of the skull bones of the holostean Amia calva and of the teleost Clupea finta, shown in Figs. 1 and 2, were investigated in this way. The homologies of the skull bones of *Amia* with those of teleost fishes have been much disputed⁷⁻¹¹. The relations "anterior to", "dorsal to" and "distal to" were used, and the parts selected were the bones numbered in Figs. 1 and 2. No unique largest correspondence was found, but the several equally large correspondences differed only in the ways in which the bones of the suborbital series (25-29 in Amia and 17-21 in Clupea) were paired. This indicates that skull topography alone is insufficient to determine the homologies of these bones which are, at least in Amia, rather variable in number and relative position. correspondence computed for the other bones is shown in Table 1. The homology suggested by Gregory¹¹ is largely supported, although Gregory considers 16 and 32 in Amia to constitute a single bone, the quadrate, in contrast to Allis⁷ and Goodrich¹⁰, who recognize, as we do here, a distinct symplectic bone.

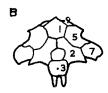

Fig. 2. Diagrams of the skull of Clupea finia. A. Lateral aspect; B, posterior aspect. (Partly after Ridewood¹⁸.)

A further study of a disputed homology, the homology of the dermal skull-roof bones of the crossopterygian fishes Osteolepis and Holoptychius, will be described elsewhere.

We feel that the demonstration that biological homologies can be derived numerically is of importance for tworeasons. First, an empirical concept of homology as correspondence in relative position escapes the circularity implicit in phylogenetic definitions of homology, but is in line with the widely prevalent use of the term in comparative anatomy. We have shown that the method for computing homologies outlined here may be of practical use in studies of comparative anatomy. Instead of defining homology in terms of derivation from common ancestral parts it should be possible, by studying fossil series, to investigate the extent to which homologies, in the sense defined here, may be used to infer the structure of ancestral organisms. Second, it clears up a difficulty in the rationale of numerical taxonomy. One of the criteria for the selection of characters in numerical taxonomy is that the characters should be, in some sense, the same in all the organisms studied (compare Sneath and Sokal¹²). In other words, the characters selected should be such that their states are identical attributes either of whole organisms or of parts homologous in all the organisms studied. For example, the character "petal colour", having as states "petals red", "petals white", etc., should only be used in a numerical taxonomic study when the parts called petals are homologous in all the plants studied. The explication of homology in terms of correspondence in relative position removes the suspicion that phylogenetic assumptions may be involved in the initial selection of characters.

We thank Dr K. A. Joysey for helpful criticism, and Mrs V. Cole and Miss A. A. Houston for assistance.

GENERAL

Character Recognition by Holography

THE application of holography to character recognition has been receiving a great deal of attention. A recent report by Gabor¹ introduced a somewhat different approach to the problem, based on a principle "that if two coherent waves are made to fall simultaneously on a photographic plate, one coming from an object A, the other from an object B, the photograph links these together in such a way that if the hologram is illuminated by A alone, B will appear too, and vice versa". I now present some experimental investigations based on this approach.

This principle may be re-stated in a mathematical form as follows. If A and B are two coherent disturbances

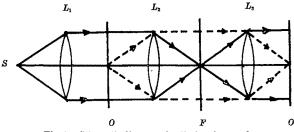

Fig. 1. Schematic diagram of optical system used.

falling on a photographic plate, then the recorded intensity of the interference pattern is

$$I = |A+B|^2 = |A|^2 + |B|^2 + A^*B + AB^*$$

where superfix * denotes a complex conjugate function.

When the photographic plate is developed such that its amplitude transmission is proportional to recorded intensity and then illuminated by disturbance A above, the complex amplitude distribution, S, leaving the plate is given by

$$S = A \cdot |A + B|^2 = A \cdot [|A|^2 + |B|^2] + A \cdot A \cdot B^*, + A \cdot A^* \cdot B$$

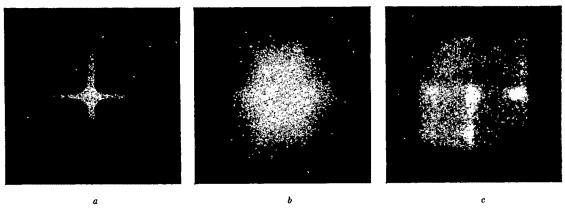

Fig. 2. Auto-correlation functions of: a, a cross +; b, a triangle \triangle ; c, a square \square .

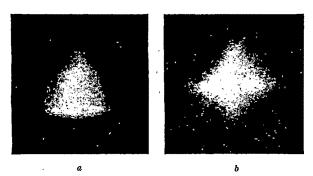

Fig. 3. Reconstruction of (a) the triangle and (b) the cross from the interference pattern of the triangle and the cross.

It may be seen that the last term, in the foregoing equation, will yield B, provided $[A A^*]$ is approximately constant. This is sometimes the case, as will be shown

The experimental work was carried out using Fourier transform holography in order to avoid the more serious optical alignment problems. The optical system is shown in Fig. 1. A transparency containing two objects, in this case two block letters A and B, was placed in the object plane O. The resultant interference pattern between the Fourier transforms of A and B was photographed in the Fourier plane F. The developed plate was then replaced in exactly the same position and the output was observed in the image plane \bar{O}' .

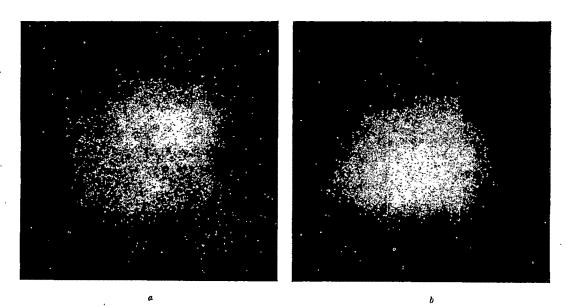

Fig. 4. Recovery of (a) the square and (b) the triangle from an interference pattern between the triangle and the square.

It is not necessary to print a positive from the recorded hologram, for this only reverses the contrast of the interference fringes. This change of contrast amounts to phase shift of π which does not influence the final intensity in the observed image.

Thus the recorded intensity in the plane F is given by

$$I = |ae^{ikr_1w} + be^{ikr_2w}|^2$$

where a and b are Fourier transforms of A and B, respectively, r_1 and r_2 are the distances of the centres of area of patterns A and B, respectively, from the optical axis and w is the co-ordinate in the Fourier plane F. Now, when pattern A is covered in the input plane and only B illuminates the filter at F, the complex amplitude distribution just behind it is given by

$$T_{P} = be^{+ikr_{2}w}|ae^{+ikr_{1}w} + be^{+ikr_{2}w}|^{2} =$$

$$= be^{ikr_{2}w}[|a|^{2} + |b|^{2}] + b \cdot b^{*} ae^{ikr_{1}w} + b \cdot a^{*} \cdot be^{ik(r_{1} + r_{2})w}$$

The lens L_3 takes the Fourier transform of light distribution at F giving the output at O' as

$$O'(z) = [\alpha \beta]_{z = -r_2} + [B^*B^*]_{z = -r_1} \oplus A + [B^*A^* \oplus B]_{z = -(r_1 + r_2)}$$

where α is an approximately constant attenuation factor due to $|a|^2 + |b|^2$ and A_*B^* and $A \oplus B$ denote the cross-correlation and convolution of A and B, respectively. The subscripts z=-r, etc., denote the position of the centres of the patterns.

Thus the first term in the last equation is the geometrical image of B attenuated by α. The second term occurs at the position where the geometrical image of A would have been. This term will also represent the reconstructed image of A, provided that B*B* tends to a Dirac delta function. Thus in order to recover faithfully the missing pattern from the combination of the two, the illuminating pattern must have a narrow autocorrelation function, ideally tending to a Dirac delta function. The third term is a complicated pattern which may be interpreted as cross-correlation between A and B convoluted with B.

A number of patterns were chosen with various autocorrelation functions ranging from very narrow to very broad. These are shown in Fig. 2 along with their autocorrelation functions. Only some combinations of patterns were used.

Fig. 3 shows the reconstruction obtained from the interference pattern of the first pair, that is, a cross and a triangle. The triangle (Fig. 3a) is very well reconstructed when illuminated by the cross, which has a narrow auto-correlation function. On the other hand, the reconstruction of the cross is very poor (Fig. 3b). Fig. 4 shows the same for a triangle and a square. Neither of the two objects is well reconstructed, the reconstruction of the triangle being especially poor because the autocorrelation function of the square is very far from a narrow peaked function.

The experimental evidence presented shows that patterns A and B may be retrieved from the interference of A and B but with an important qualification. Pattern A may only be faithfully recovered if B, illuminating the combination, has a narrow auto-correlation function, and vice versa. Thus the method described is not very suitable for character recognition because many letters do not have a narrow auto-correlation function. The method could be used more efficiently with specially designed patterns.

Van Heerden² in 1963 proposed a somewhat similar approach for information retrieval. He used what he calls an intensity filter in the Fourier plane; it was simply a positive of a photograph of the Fourier spectrum of a pattern present in the input plane O (Fig. 1). When such a filter is illuminated with a fragment of the same pattern

a "ghost" image of the complete pattern may be seen.

Stroke et al.³ have also used a similar filter for what they call "holography with extended sources" and arrived at the same conclusion that the illuminating pattern must have an auto-correlation function tending to Dirac delta function.

I should like to thank Mr D. A. Gregory for the help with experimental work.

Identity for the Product of Two Positive Definite Quadratic Forms

THE problem of generalizing the following basic identity

$$\sum_{1}^{p} a^{2} \sum_{i>j}^{p} b^{2} = (\sum ab)^{2} + \sum_{i>j} (a_{i}b_{j} - a_{j}b_{i})^{2}$$

given in Hardy, Littlewood and Pólya¹, remains to be considered. We shall show that the generalized Cauchy inequality follows immediately from this generalization. The resulting identity has many fruitful applications in problems of multivariate ratio estimation in sample survey theory.

Let $C = [c_{ij}]$ (i, j = 1, 2, ..., p) be a symmetric matrix possessing a non-singular inverse $C^{-1} = [c^{ij}]$ (i, j = 1, 2, ..., p). Denote the jth column vectors of C and C^{-1} by c_j and c_j , respectively. Let $H = C_1^2$, so that H is a $p \times p$ symmetric positive definite matrix and let $z = (z_1, z_2, \ldots, z_n)$ z_p) and $u = (u_1, u_2, \dots, u_p)$ be any two non-null row vectors of length p. Then we have the following identity

$$(zHz')(uH^{-1}u') = (zu')^2 + \sum_{i>j} \{z(c_iuc_j - c_juc_i)\}^2$$
 (1)

which is the generalization of the basic identity given here, the summation in the last term being over the C_2^p pairs of (i, j).

The proof is quite simple. In matrix form the basic identity can be expressed as

$$aa'.bb' = (ab')^2 + \sum_{i>j} (a_ib_j - a_jb_i)^2$$
 (2)

where a and b are non-null row vectors of length p. Setting a=zC and $b=uC^{-1}$ in the identity (2) and remembering that $H = C^2$ and that the scalars $a_i = zc_i$ and $b_1 = uc^j$, the identity (1) will be obtained.

The generalized Cauchy inequality follows by noting

$$(zHz')(uH^{-1}u') \ge (zu')^2 \tag{3}$$

equality holding if and only if $zc_i = \theta uc^i$ for all i, where $\theta \neq 0$ is a constant, which implies that we must have $zC = \theta uC^{-1}$ or $zH = \theta u$.

Finally, in identity (1), if we set M=I the identity matrix, and remember that $I = I^2$, we get back to the basic identity.

BOOK REVIEWS

BIRTH OF THE CALCULUS

The Mathematical Papers of Isaac Newton Vol. 1, 1664-1666. Edited by D. T. Whiteside. With the Assistance in Publication of M. A. Hoskin. Pp. xlvi+590. (London and New York: Cambridge University Press, 1967.) 210s. net; \$40.

WHEN the Royal Society took the decision of limiting the publication of the Newton papers to the correspondence, it was apologetically pointed out that editing of the manuscripts "would require long labour of many patient and profound experts such as it is hard to find today". It is therefore a matter of great satisfaction that one at least of such patient and profound experts has had the pluck to accomplish single handed one of the most important of the tasks shunned by the Royal Society: the critical examination and publication of Newton's mathematical manuscripts. This took him ten years of labour, if we include in the reckoning the painstaking and profound study he carried out, as a preparation, of the whole background of contemporary mathematical knowledge and thinking, in which Newton found the starting point and the inspiration for his own discoveries. The results of this study are embodied in a thesis (Archive for History of Exact Sciences, 1, No. 3; 1961) which ranks as a major contribution to the history of seventeenth century mathematics.

With the present volume—the first of eight—the undertaking enters its last stage, and there is every reason to congratulate the author and his collaborator as well as the publishers for a superb achievement, the completion of which will now be impatiently awaited. In format and lay-out the book resembles the volumes of the correspondence, and like the latter is a masterpiece of typography; in details the transcription of the documents is even better than that of the letters. The delicate problems raised by the dating and arrangement of the single items have been solved with great competence and ingenuity. In principle, all the extant material is reproduced, with only trivial exceptions. We thus dispose of every scrap of evidence to help us to retrace the steps that led Newton to his conception of the calculus. In this case, we have even more: in the attempt to present a systematic account of his methods, Newton never managed to proceed further than to drafts, and only one or two of these were eventually published; we are now in a position to read and compare these successive drafts, and to judge, much more easily than from the published pieces, how early Newton acquired a full mastery of the new methods.

The first volume covers only three years, but these were just the decisive ones, 1664–1666. From the notes scribbled in the books Newton used as a student, we can for the first time determine with full certainty the sources of his discoveries, the authors that had the greatest influence on him, and the way in which these influences combined to start him very soon on untrodden paths. This analysis has been done by Dr Whiteside, and he gives us his results in abundant footnotes as well as in the introductions to the four parts (counting the appendix as one part) in which he has distributed the material. Of these, the

first two are perhaps the most interesting, although there is much of value also in the last two, devoted to algebra and geometrical optics respectively. From the first part, reproducing Newton's annotations in books, we learn above all of the paramount influence of Descartes' analytical geometry, and especially the commentary added to the Latin edition by F. van Schooten, that able Dutch mathematician who was Huygens' preceptor. It is from the Dutch Cartesian school that Newton got the example of an algorism—a time-saving general prescription—for finding the tangent to a curve from its equation. This rule was limited to the so-called "geometrical" curves, that is, those whose equation could be written in algebraic form.

At the same time, however, Newton learned from the British school, taking its origin in Napier's invention of the logarithms, how to treat non-algebraic functions "mechanically", that is, by series expansions; he had only before him Wallis' crude "interpolation" procedures, and his establishment of the general binomial expansion was a truly creative effort. The crucial point was (to put it in modern terms) to pass from the definite integrals considered by Wallis to the corresponding indefinite integrals: thus was obtained a series in powers of the variable upper limit, with a clear algorism for the computation of the coefficients, instead of Wallis' obscure arithmetical operations. What Newton further learned from Wallis was the method of integration developed by Cavalieri, who, with that other Galilei disciple, Torricelli, had founded a brilliant, though short-lived, school of mathematics in This method of indivisibles could be readily incorporated in the new calculus as soon as Newton realized that integration and derivation are inverse operations.

The fundamental element in Newton's method, however, the concept of fluxion, came last in the picture. It arose from the need to solve the tangent problem in full generality, that is for the non-algebraic curves called by Descurtes "mechanical", because they were mostly defined as loci of the intersection of two straight lines translated in two different directions according to given laws of motion. To construct the tangent in such cases as the diagonal of the velocity parallelogram is not a deep idea: indeed, it is indicated in the pseudo-Aristotelian "Problemata". At any rate, we find a method of construction of tangents on this principle elaborated about 1650 by Torricelli, and further developed, in direct continuation of Torricelli's work, by R. de Sluse and by Roberval. Now, in Newton's notebooks the same method is discussed and applied to various problems, but there is no indication of its source. It is quite possible that he heard about Torricelli's method through Barrow's lectures, though he later declared that he did not remember it. It is also possible that he rediscovered this rather simple approach independently. However this may be, the decisive step he took was to translate the geometro-mechanical construction in analytical terms. How essential this last step was is shown by the case of R. de Sluse who, like Newton, was conversant both with Torricelli's approach and with the algorism for finding the derivative of an algebraic function (which he had found independently): he missed the fluxion idea, however, because it did not occur to him to combine the two methods.

These very fragmentary remarks may perhaps convey some idea of the treasures opened to the historian's view by this monumental publication. Thick as it is, however, this book reflects only a part of the lonely youth's astounding intellectual activity: his studies of Cartesian philosophy and mechanics, his awakening interest in optics, astronomy and chemistry could be documented by volumes of equal importance. Could one hope that Dr Whiteside's brilliant example might stimulate other 'patient and profound experts' to undertake for the other domains in which Newton has left his mark a similar labour of love, a labour bringing with it such rich rewards?

L. Rosenfeld

DE MINIMIS NON CURAT LEX

The Natural History of Viruses

By C. H. Andrewes. (The World Naturalist.) Pp. viii+237+41 plates. (London: Weidenfeld and Nicolson, 1967.) 55s. net.

More than a hundred years has gone by since the first publication of the Origin of Species, a work whose contents have been so frequently quoted as an excuse for man's inhumanity to man that it has become one of the seminal books of world literature. But during that same century it has also been shown many times that even the unremitting pressures of natural selection sometimes help the meek to survive. Nature is not always red in tooth and claw, and parasites, in particular, exemplify the principle. A parasite which is successful from the point of view of the survival and dissemination of its own species can be one that does little harm to its host. The dividing line between successful parasitism and commensalism—the concept of the tolerated guest—is as arbitrary as the iron curtain.

In this book Sir Christopher Andrewes calls on a lifetime of experience of the devious ways of viruses to sustain the contention that even they are subject to the inexorable Darwinian law: that they, just like other organisms, have their natural history; hence the title of this book, written with wit and a clarity of style that should be a model to those that follow him. Although writing primarily for laymen, he never compromises on fact, or takes refuge in obscurity, so that his main thesis is wholly acceptable, even to professional colleagues. A wealth of data is assembled to show that viruses have to struggle for existence like any other organism. They use all sorts of dodges to obtain access to new hosts and to survive hard times. But viruses differ from all other parasites in that they do not replicate by themselves. They are copied by the living cells they inhabit. Moreover, it is a cliché of pathology that virus lesions do not appear until virus replication is already over. So the primary target of natural selection must be the multicellular organism of which the infected cell forms a part. Selection will only affect the virus within it if the host succumbs before sufficient virus can be made and disseminated, and the successful virus will be one that can persuade its host to produce and excrete a vast quantity of virus particles. Whether the host survives or not is irrelevant in this context; if enough rats succeed in leaving the ship, who cares if it sinks or not? Host mortality will only affect the evolutionary fate of a virus if its onslaught on the host species is so fierce that later virus populations die out through lack of new victims to sustain them. It can be argued that a virus which is less totally destructive, but which still kills a large proportion of its hosts, may even have an evolutionary advantage. First, it will avoid a too rapid spread of immunity through the host species; and second, the more virus there is, the greater will be the chance that new mutants may arise, capable perhaps of attacking new species, or of surviving until new susceptible individuals of the original host species become available.

But when I had finished his book I began to wonder whether in fact this was the only way to assess the importance, in nature, of this fascinating collection of infectious agents. Do viruses obey evolutionary laws because they are organisms? Or is it that such laws describe the behaviour of all things that have reached a certain level of complexity? In this sense, evolution is as inevitable a description of the behaviour of organized matter as Newton's laws of motion. The mere presence, within the primeval prebiotic soup, of a minor constituent with a thermodynamic advantage will ensure its eventual dominance. No one would suggest that such compounds are organisms, or indeed living in any sense, and it is perhaps more appropriate to describe their behaviour in physico-chemical terms.

All this would be mere quibbling were it not that one of the dangers of the "organismal" approach to viruses is that it can blind one to their unique character. Their special position was recognized many years ago by S. E. Luria when he referred to the life of viruses as "parasitism at the genetic level", and it is this aspect of their behaviour that has fascinated virologists over the past ten years. Sir Christopher Andrewes, however, rightly reminds us that there is much more to virology than gift-wrapped packages of rogue nucleic acids. The law of evolution may not care for such little things, but we must never abandon his way of looking at them.

F. K. SANDERS

NMR, NQR AND EPR

Magnetic Resonance Spectroscopy

By Harry G. Hecht. (Wiley Series in Pure and Applied Spectroscopy.) Pp. viii + 163. New York and London: John Wiley and Sons, 1967.) 45s.

VIRTUALLY the whole of NMR, NQR and EPR spectroscopy is covered in 160 pages, and thirty of these summarize a considerable amount of quantum mechanics. The book is the latest of a series on pure and applied spectroscopy and deals with a larger area than any of its predecessors in less than half the space of the shortest of them! Here is the book's weakness—too much in too little space. Topics mentioned include solid state NMR, pulsed radiofrequency fields, electron-nucleus double resonance, electron and nuclear relaxation, as well as the commonly used concepts such as chemical shift, spin coupling, g tensor and so on.

The book is aimed at the undergraduate-graduate overlap region as a "survey of the field of magnetic resonance spectroscopy as a whole that is geared to the interests of a chemist..." and to such students who "find it necessary to rely on magnetic resonance data...." There is no doubt that a general discussion of the relevance to chemistry of this form of spectroscopy should be part of a chemist's education, but the considerable amount of mathematical derivation limits its value here. Only forty references (mainly to books) are given, but these simply follow chapters without specific connexion to the text, so the reader will find original papers only with difficulty.

The author has briefly discussed most of the areas of the subject chemists are likely to meet, so the book will serve quickly to widen the perspective of mathematically inclined students with a limited acquaintance of magnetic resonance.

R. Bramley

STUDENT'S INTERFEROMETRY

Interferometry

By W. H. Steel. (Cambridge Monographs on Physics.) Pp. ix+271. (London: Cambridge University Press, 1967.) 60s. net; \$11.50.

This well written book attempts to cover quite a formidable subject in eleven chapters and succeeds reasonably well in doing so. The whole approach differs somewhat from that of older long accepted texts of interferometry. It is certainly well up to date. The second, third and fourth chapters are mathematical, dealing essentially with Fourier transforms (so popular today), diffraction and coherence. This then is an introductory theoretical basis of wave theory leading on to what is more usually meant by interferometry. This kind of approach is a growing practice now in optics. Whether it helps to clarify the situation for a student is another matter. I am not sure that it does. This introductory theoretical section is well written and compact but will certainly not be easy for the beginner.

Fringe visibility in two-beam systems occupies the fifth chapter. In the following chapter Michelson's interferometer is treated comprehensively, and here I welcome the introduction of this interference system as used for microwaves as well as for light waves. The seventh chapter, which deals with multiple-beam interference systems, is right up to date with regard to refinements of theory, new instrumentation and bibliography. Yet, curiously enough, the author, like so many others expert in interferometry, fails to refer to Boulouch, the real inventor of the multiple-beam fringe sharpening principle, indeed creating in effect what we now call both Fabry-Perot and Lummer plate interferometers. This historical detail deserves rectification if a second edition be called for.

As might of course be expected from a writer who works at a National Standards Laboratory, the section on interference comparators, the measurement of length and the interferometric assessment of refractive indices is very good. Here, too, I welcome brief, clear descriptions of microwave analogues to optical interferometers. ninth chapter covers a great deal of ground, including the use of multiple-beam interference methods for the study of surface microtopography, the testing of optical surfaces, shear interferometers and also the rapidly growing new field of interference microscopes. This latter section might with advantage have been expanded somewhat, now that transmission interference microscopes of a variety of types are coming on to the market for use by biologists, who more and more are beginning to appreciate what interferometry can offer them.

Although the tenth chapter, which deals with interference spectroscopy, is certainly up to date and includes many recent refinements in instrumentation, it is rather lame with respect to the actual optical requirements involved in practice when combining an interferometer with a spectrograph. This involves numerous pitfalls, and the student hoping to become a high resolution spectroscopist is not going to find any real "know-how" here to help him. No tricks for adjusting interferometers, no warnings about possible varieties of ghost or reflected images, no hint at all about how to make the essential high reflecting films and so on. For this the student would have to look elsewhere. Indeed, because of the gloss over such details, interference spectroscopy is made to sound a good deal easier than in practice it is. Nevertheless there is sufficient of very real value in this book for every student of optics and spectroscopy, and the final chapter, entitled "Interference Imagery", contains a valuable and clear discussion of stellar interferometers, both of the optical and radio types.

Altogether this is a most readable text and, although the introductory part makes it heavy weather for the undergraduate, it is to be well recommended to any student who wishes to specialize in optics, metrology or spectroscopy. The book is particularly well illustrated with line diagrams, but regretfully has no plates at all—a pity, because interferograms are often photogenic. The comprehensive fourteen-page bibliography with well over five hundred references will be of real value to the student who wishes to go further.

I welcome this new text.

S. Tolansky

DIFFERENTIAL EQUATIONS

Introduction to Ordinary Differential Equations By Albert L. Rabenstein. (Academic Press Textbooks in Mathematics.) Pp. xii+431. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 80s.

This book represents a well organized introduction to what used, in textbooks, to be a somewhat disorganized subject. In the main, apart from the basic existence

theorem for solutions of ordinary differential equations. all the results are proved.

There is a discussion of the various cases of Frobenius's method of solution in series and a considerable treatment of results concerning sets of orthogonal polynomials, both general sets and particular sets. Sturm-Liouville theory is discussed in one chapter with a brief mention of some singular cases, but it is odd to note that the two originators of the theory are not mentioned at all.

Other topics included are systems of differential equations, Laplace transforms, separation of variables, and autonomous systems, and there is a short excursus into the theory of partial differential equations.

There are sufficient exercises together with answers to about half of them to provide an eminently readable textbook for a second or third year undergraduate mathematics or engineering student.

R. L. Perry

MORE DIFFERENTIAL EQUATIONS

Elementary Partial Differential Equations

By Paul W. Berg and James L. McGregor. (Holden-Day Series in Mathematics.) Pp. xv+421. (San Francisco, London and Amsterdam: Holden-Day, Inc., 1966.) \$13

This book is formed by a revised collection of notes of lectures given at Stanford University, and is suitable for mathematics students or mathematically inclined physicists and engineers.

It is based on the concept of separation of variables which is adapted to cater for various boundary conditions and various initial conditions. There are several introductory chapters containing concepts and theory needed later, covering among other topics Fourier series and some ordinary differential equation theory including Sturm-Liouville theory. The theory is mostly in respect of the heat, wave and Laplace equations in two or three dimensions and seems somewhat repetitive, but the methods and theorems can apply to similar equations. Extensions to semi-infinite and infinite intervals are also included. Each chapter contains exercises and some but not all answers are supplied.

The authors have produced a book which covers those aspects of partial differential equation theory which are perhaps those of most interest to the physicist and engineer.

R. L. Perry

CENTRES OF IMMUNITY

Germinal Centres in Immune Responses

Edited by H. Cottier, N. Odartchenko, R. Schindler and C. C. Congdon. (Proceedings of a Symposium held at the University of Berne, Switzerland, June 22–24, 1966.) Pp. xvi+499. (Berlin and New York: Springer-Verlag, 1967.) 78 D.M.; \$19.50.

This book contains fifty-seven contributions on various aspects of the role of germinal centres in immunity. In addition, a considerable amount of space has been devoted to the discussions which followed each session, and a valuable concluding summary of the whole proceedings is also provided. The name "germinal centre" was coined more than 80 years ago, to describe the prominent clusters of pale staining cells found in lymphoid tissues. These centres show intense proliferative activity, and so they have been thought to be sites of small lymphocyte production. Although this assumption is no longer wholly tenable, there is a growing body of evidence that they play an important part in certain immune responses.

One of the aims of the book, as stated in the preface, is to combine this evidence "in a single package". It succeeds in being comprehensive, but this is at the expense of repeating data which have been published in the proceedings of other recent conferences. The need to repeat

information in this way is open to question.

In reviewing a volume of this length it is impossible to appraise separately each individual contribution, but the overall impression is that the book provides pointers to possible lines for future research rather than a body of firm facts. In an opening session the attractive concept of separate thymus and bursa dependent central immune systems is reviewed and it is concluded that the development of germinal centres is most closely related to the bursal system (or its mammalian equivalent). In this context, the centres are probably more concerned with antibody responses (mainly bursa dependent) than delayed hypersensitivity reactions (probably thymus dependent). Unequivocal evidence is presented for the localization of antigens and immunoglobulins within germinal centres, but it is not certain whether the antibody is actually produced within these sites.

Clearly, much hinges on the elucidation of the origins, functional properties and ultimate fate of lymphoid cells within the centres. It is unfortunate that in the session dealing with ultrastructural studies, some contributors attempt to draw up schemes of cellular transformations by means of the static appearances seen in tissue sections. Appropriate labelling techniques (radioisotope or chromosome marker) are always needed to determine cellular transformations with certainty. Further knowledge of the kinetics of the cells of the centres must await the

successful application of these methods.

In conclusion, this book contains a valuable account of current progress in research on germinal centres. Ample evidence is provided for the importance of these centres in immune responses and in the actiology of a number of disease processes. The centres probably result from a proliferative response to prolonged stimulation by antigen. The precise relationship of this response to antibody formation and other immunological phenomena remain problems for future study.

J. J. T. OWEN

TOXICOLOGY AND TOXINOLOGY

Animal Toxins

Edited by Findlay E. Russell. (A Collection of Papers presented at the First International Symposium on Animal Toxins, Atlantic City, N.J., USA, April 9-11, 1966.) Pp. xiii+428. (Oxford, London and New York: Pergamon Press, Ltd., 1967.) 120s.

The publication in book form of the proceedings of symposia was deplored some years ago in the pages of Nature (193, 724; 1962). This volume is described as "a collection of papers" presented at a symposium. This may mean that some contributors did not submit suitable manuscripts; it certainly means that the reader is spared the trivia and undocumented pronouncements commonly found in recorded discussions. The papers certainly have the accepted format for those appearing in the publishers' scientific journals. About 2,000 pages of their Biochemical Pharmacology costs a library £35 and a private subscriber £5. The 400 pages of this bound volume cost £6—a marginal bargain for the library, but not for the individual!

There are forty-four papers dealing with the poisons produced by arthropods (eight), marine organisms (thirteen), snakes and amphibia (twenty-two), together with a final paper on the action of any of these toxins on the nerve, the muscle and the neuromuscular junction of the guineapig. The papers deal chiefly with pharmacology and toxicology (twenty), chemistry (nine), immunology (four), and biochemistry (three) of the toxins as well as the anatomy (four) of the poison glands, and zoology (three) of the poisonous animals.

It would be mere effrontery for a toxicologist to undertake a detailed critical review of this book, which embraces the subject of toxinology. In toxicology, the essential

chemistry of the poison, be it synthetic or of plant origin, is usually not a problem. The fact that much less is known about the chemistry of animal poisons is not solely the result of a preference of chemists for ragwort rather than rattlesnakes as a source of their starting material but also of the innate complexity of many animal secretions. The precise modes of action of animal toxins, however, remain neither more nor less of a mystery than those of most other natural or synthetic poisons. Here toxinology and toxicology are on common ground. Meanwhile bacterial toxins will presumably remain outside the fields of both toxicology and toxinology and continue to be studied by microbiologists.

It is difficult to know what place a book such as this has in overcrowded libraries. To the general reader interested in learning something of a subject new to him or her there is too much detail in the papers. The specialist will probably have seen the detailed work reported elsewhere. As was said in 1962, there is probably a place for the recording of critical reviews and survey papers presented at symposia, and only one of this type is found in this volume.

J. M. Barnes

FAILURE STORY

Investigations into Generation 1651-1828
By Elizabeth B. Gasking. (The History of Scientific Ideas.) Pp. 192. (London: Hutchinson and Co. (Publishers), Ltd., 1967.) 30s. net.

From the time of the Greeks until the nineteenth century the word "generation" was used for what we would now call reproduction. It included a penumbra of other subjects: genetics, embryology and the anatomy of the reproductive organs; but the central issues concerned the contribution of the sexes and the mystery of embryological development.

A number of accounts of this complex historical topic have been written, the most renowned of which is Professor Cole's Early Theories of Sexual Generation (1930). In her presentation of this subject Mrs Gasking has been concerned to avoid the pitfalls of the dramatic approach—accounts painted in the lurid colours of the clash of rival theories; and of the discovery approach—the documentation of the first discovery and first adumbration of facts and ideas which still find a place in modern biology; for she is interested in theories of generation in the seventeenth and eighteenth centuries for their own sake. She was puzzled by the naivety of supposedly eminent scientists who accepted so implausible a theory as the preformation of the germ (egg or sperm). This puzzlement led her to carry out the research which is described in this book.

What has her presentation to offer? First, it contains much of the work already gone over by Cole. Because Cole's book is out of print and because Gasking comes to different conclusions than he on a number of points, this part of the new book is very welcome. Her book also contains an account of the more recent work carried out by Professor Glass on Réaumur, Maupertuis and Adanson. She has also described her detailed work on Harvey and Prévost and Dumas.

Mrs Gasking holds that Harvey must not be considered as an orthodox representative of the views of the ancients on generation, but as one who broke away from their authority as a result of his observational and experimental work. Coming now to preformation, Mrs Gasking advances three reasons for the acceptance of this implausible theory. (1) That there was no plausible alternative explanation at the time. (2) That the doctrine of preformation was in harmony with the organ-ridden physiology of the day. (3) That empirical discoveries, particularly in the eighteenth century, tended to support the theory.

While accepting that these three points were important, I wonder whether the religious foundations of the doctrine of preformation were not much more important, and were more central to the problem of the naivety of eminent biologists.

Like the other titles in this series on "The History of Scientific Ideas", this book is very well produced. those who enjoy reading about the interplay of facts and theories, about the plausibility of a theory in terms of the knowledge and world view of the day, and who have the patience to work through poorly organized but scholarly material, Gasking has provided a detailed and thorough case history. The reader will learn, as the author did, "more about what happens when scientists become interested in aspects of a problem which they lack the means to solve". ROBERT OLBY

READINGS IN ANTHROPOLOGY

Human Evolution

Readings in Physical Anthropology. Edited by Noel Korn and Fred W. Thompson. Second edition. Pp. xiii + 466. (New York and London: Holt, Rinehart and Winston, Inc., 1967.) \$4.95 paperbound.

IT has long been customary in university teaching to supplement textbooks and organized lecture series by readings in the literature of the given subject. This may be done in science by reference to the original technical literature, by reprints of semi-technical papers or by monographs on specialized sub-topics. In the United States, particularly, supplementary materials are increasingly provided by books which are selections of previously published papers and essays. Anthropology has been well served in this way by a variety of yearbooks, for example, one published by the Wenner-Gren Foundation, and by more occasional books of readings. for example one edited by William Howells (1962) or another by J. D. Jennings and E. A. Hoebel (1955 and 1966). The present collection by Korn and Thompson is of the latter sort. Although titled as a second edition, it is new for the most part, about half of the selections being from publications originally issued in 1963 or later.

Review of a book like this should be directed rather to editorial features and to adequacy for an intended purpose than to the contents of the individual chapters, all of which have already been published elsewhere. In the first place, the sub-title of this volume is inaccurate, for one of the seven parts ("Evolution, Genetics, and Natural Science", three essays) is not on any aspect of anthropology as such and another whole part ("Studies of Primates", confined to primate behaviour, four essays) and several others of the twenty-six separate essays do not meet any

accepted definition of physical anthropology.

Selections are for the most part by competent experts and adequately represent the current status of the subject. There are unfortunate exceptions; for example, the essay on the extremely touchy subject of skin colour is not by an anthropologist and does not represent the most recent and soundest views of anthropologists. Many of the essays are abridged, and the extent of curtailment is not adequately indicated by a symbol (...) for omissions. For example, less than a third of Goodall's remarkable essay on chimpanzee behaviour is reprinted. (It is interesting that the deletions include the section on sexual behaviour.) Most of the illustrations have been redrawn ("adapted"), not always skilfully, and figures have even been interpolated without notice; for example, the two very poor figures (17-2 and 17-3) of fossil hominids apparently attributed to J. T. Robinson are not based on anything in his original publication. Citations given by the original authors have all been deleted, sometimes with mystifying results; for example, two figures (23-3 and 23-4) attributed in the text to myself are completely strange to me.

The noted shortcomings are surely no more than venial, and the selected essays are well worth reading. It is to be hoped, however, that both teachers and students can do better. G. G. SIMPSON

ADVANCED LOOK AT EVOLUTION

Process and Pattern in Evolution

By Terrell H. Hamilton. (Current Concepts in Biology.) Pp. x+118. (New York: The Macmillan Company; London: Collier-Macmillan, Ltd., 1967.) 15s.

Thus is a useful little book in the "Current Concepts in Biology" series, apparently aimed at first-year under-graduates and higher. The author says "There can be no doubt that the first-year undergraduate now has a better secondary education than we previously assumed, and that he is capable of more independent work than we usually demand". One can hope that this is so, but I think many will find the book too stiff. It deals, after a brief chapter on Darwin and Wallace, with the elements of population genetics and population ecology, types of natural selection, speciation and adaptive radiation as the consequence of selection and species specialization. Only geographical speciation is treated, and no plants and usually only the higher animals are mentioned. The discussion of highly controversial points is often oversimplified and too exclusively theoretical. The title is much too wide, but the book does form a coherent whole. English workers will in general be familiar with the line of approach, although some will welcome the discussion of population ecology and the attempt to bring it into relation with selection and population genetics. series is almost wholly American and, because Ernst Mayr describes the approach as novel, it is presumably expected to be thought rather advanced in viewpoint in the United States, as indeed is likely—it is rare to find an American author so free from the prevailing dogma of the importance of genetic drift in evolution. The author has some of the usual weaknesses of American terminology; adaptive value (fitness for a particular purpose) is equated with selection coefficient (relative representation in the next generation); but only once is something that is necessary. desirable, or useful described as mandatory, and the book is very readable and well laid out. A. J. CAIN

EVOLUTION OF PINE TREES

The Genus Pinus

By N. T. Mirov. Pp. viii + 602. (New York: The Ronald Press Company, 1967.) \$15.

This is a fascinating book to anyone working with pine trees. It sets out not to give full detailed data on individual species, although many details are given as examples. but to trace the genus from its origins in time and place and thereby explain the current distribution and potentialities of the pines. Silvicultural and wood quality studies are omitted.

After a chapter on the historical references to pine in literature from the days of Theophrastus to the end of the nineteenth century, the palaeobotany and geography of the genus are traced by means of fossil records and pollen grain studies. This reveals the possible migration of pines during 200,000,000 years from a northern hemisphere centre around the Bering Sea through North America to Nicaragua, through China and south-east Asia to Sumatra and through the Himalayas and Turkey to Europe and the Canary Islands. In Cretaceous times (100,000,000 years ago) pines had already become differentiated into two groups, haploxylon and diploxylon, but had not travelled further south than 32° N. in Texas and 35° N. in Asia. No fossil pine remains have been found in the tropics or south of the equator. From Cretaceous times Mexico has become a secondary centre of proliferation of diploxylon pine species, owing to its wide range of habitats within short distances.

Many small scale outline maps and excellent photographs cover the distribution and appearance of 105 species, the areas where hybridization between species has occurred and the world pine regions. Some species have greatly expanded their distribution since the ice ages, for example Scots pine; others are senile and isolated in parts of California and elsewhere; some can be crossed easily with related members of the genus although widely separated for many million years; others are difficult to hybridize.

There are chapters on genetic aspects, on morphology and reproduction, and on physiology and ecology. Much is still unknown and, interested in tropical pines, I found no explanation of the grass stage of seedlings common to several species or apical dominance so characteristic of *Pinus caribaea* and some others when grown in favourable conditions.

The relatively new study of the chemical aspects of pine cell contents has been a special interest of Mirov's and receives full treatment in the seventh and eighth chapters. He points out that chemical evolution may not have run parallel to morphological evolution but that it can provide valuable evidence to supplement morphological data in attempts to explain the relationships between species and provenances of species.

All these threads of enquiry are drawn together in a chapter on taxonomy where the older system based on type specimens is contrasted with the multiple aspect approach favoured by Mirov and the radically different system of Gaussen which is criticized.

From their fossil history pines are shown to be adapted to seasonal climates with severe dry periods, but unsuited to equatorial zones of high humidity.

The book is well produced. An extensive list of references is given at the end of each chapter and there is an index.

A. F. A. LAMB

HERTFORDSHIRE FLOWERS

Flora of Hertfordshire

The Wild Plants of the County of Hertford and the Adjoining Areas included in Watsonian Vice-County 20. By John G. Dony, with a foreword by Edward Salisbury. Pp. 112+56 maps. (Hitchin: Hitchin Urban District Council, 1967.) 42s. net.

The last Flora of Hertfordshire, that of A. R. Pryor, was published in 1887. It is now amply superseded by Dr Dony's work, very different in style and reflecting the recent trend towards mathematical impartiality seen in other regional floristic studies. We cannot fault the precision with which the records have been assembled, but we may be less confident as to the purpose lying behind such a publication.

The 656 distribution maps, using a 2 km grid square as unit, are a novel feature of this work, and they invite direct comparison with other mapping methods, such as those used by Good in his studies on the Dorset flora. Whilst documentation is easier with a regular grid, some distribution patterns (for example riparian species) are rather obscured. But, whichever method is used, why map a species distribution at all? Surely the scientific justification is to display a pattern which can be related to possible causative agents, historical or ecological? I feel, reluctantly, that Dony has missed an opportunity here in not attempting to relate distributions to any such controlling factors. As an example, he has not included any geological map. I expect superficial geology to be at least as important as precipitation in a small lowland

county, and this is a loss compared with Pryor's work of 80 years ago. Six regions are delimited, precisely mapped and given pseudo-geological names, but they do not coincide with geological outcrops. Furthermore, these regions are not employed in the body of the Flora.

In his previous Flora of Bedfordshire, Dony used "habitat studies", detailed lists of species in well localized These attempt a compromise between the traditional British vagueness in floristic description, and the much greater precision in those emanating from the continent of Europe. They are intended to help in assessing the scale of future vegetational changes. Are they really detailed enough for this? Virtually no data are provided about soils, and the use of "frequent", "occasional" and so on is still too vague. Linking these lists is an account of the main features of plant distribution in Hertfordshire, but the actual factors responsible for this are covered in little more than thirty lines on page 24. Dony, an acknowledged expert on adventive species, could well have devoted more space to the effects of man in an intensively farmed county, and less to an account of the history of botanical exploration.

Apart from such important and more fundamental issues, I have a few small criticisms to make. There are no definitions of "colonist", "denizen" and so on, it is ambiguous to say that *Lathyrus nissolia* has "no distribution pattern", *Berberis vulgaris* does not "cause" wheat rust, and why not omit the grid reference to habitat study 51, instead of including a deliberately falsified version?

As a detailed and reliable factual record of plant distribution, Dony's Flora of Hertfordshire is admirable. But I fear it is only a skeleton. Is there not a danger of overlooking the wood for the trees ... and an account of plant distribution for a card index of impeccably documented dots?

EVERYMAN'S GUIDE TO CRIME

Crime and the Social Structure

By John Barron Mays. New and revised edition. (Society Today and Tomorrow.) Pp. 256. (London: Faber and Faber, Ltd., 1967.) 35s. net.

UNLIKE other books in this series, which report original researches, this volume is a summary review of research into crime, presented within the author's overview of the problem. Its main appeal therefore should be to the socially aware layman, the student and those working in disciplines other than, but related to, sociology. For all, and the latter in particular, it should be salutary. It is well written and very readable.

The analytical framework is simple but persuasive, and would be supported by most sociologists. Our society is crimogenic, in that our social structure produces most crime, which must therefore be regarded as one "normal" response to social stimuli. For an adequate understanding of its causation, and of appropriate remedial action, we must therefore rely primarily on sociology, with the assistance of psychology. But the latter has substantial relevance only to the minority problem of the hardened criminal and the psychopath. The author makes it clear that most crime is confined to the younger age groups, is predominantly against property and not too serious, and is amenable to containment and reduction by effective community action. His prescription mainly emphasizes the desirability of a restructuring and fuller integration of the educational service in the widest sense, embracing the schools, youth service and the corrective institutions for the young. This is admirable as far as it goes, but many sociologists would look for a more extensive approach in view of the author's correct emphasis on social structural analysis in the fullest sense.

. 1.

There are a number of minor blemishes, which a more meticulous revision (for this is a revision of the original 1963 edition) would have avoided. On page 30, for example, we are told, "... in 1938 those found guilty per thousand of the population numbered 78.5 . . . ", whereas a later Table (page 36) shows this to be both a typographical and factual error. In a number of places sources are not given (a glaring example on page 212: "Clearly the existing educational and recreational services available for 70 per cent of the young people . . . are inadequate"), and a number of footnotes are incomplete. These are unfortunate, but the book remains a most readable introduction to the subject. W. H. SCOTT

OBITUARIES

Professor B. G. Peters

BERNARD GEORGE PETERS, professor of parasitology at Imperial College since 1955, died at his home in Sunninghill on September 9 after a few months' illness. He was born at Isleworth in 1903 and was educated at Bristol Grammar School and the University of Bristol. After graduating, he worked at the London School of Hygiene and Tropical Medicine and at the Institute of Agricultural Helminthology, St Albans, first on potato-root eelworm, then on the vinegar worm, obtaining his doctorate. He continued work at the institute (which had become the Imperial Bureau) on the helminth parasites of various birds and mammals, in particular on the liver fluke of sheep and cattle. At the same time he was lecturer in helminthology at the London School.

Dealing with taxonomically difficult material the relations of which with the environment were often obscure, he found it necessary to acquire a greater knowledge of statistical methods than was common at that time. These qualifications led to his spending more than two years during the war conducting operational research at the headquarters of RAF Bomber Command. After the war he was attached to the Imperial Bureau and also to Rothamsted Experimental Station first as principal scientific officer and, from 1952, as head of the department of nematology. From then onwards his research was concerned entirely with eelworms, animals which are responsible for about half of the annual losses from British crops. Peters, however, had never lost his interest in parasites of all kinds, and when a chair in parasitology was established at the Imperial College in 1955 it was to him that the College naturally turned as its first incumbent. At that time no detailed course dealing with eelworms was available anywhere in the British Commonwealth, so that besides organizing a sub-department of parasitology which was not tied exclusively to medical or veterinary problems, he started a course in nematology leading to a diploma (now M.Sc.). The course was taken by staff seconded from the Ministry of Agriculture as well as by students from all over the world. With the aid of funds from Shell Research, Ltd., and from the University of London a new laboratory was established at the college field station, where the course, as well as much parasitological research, was carried out.

An increasing interest in parasitology in British universities led to the establishment of the British Society for Parasitology, of which Peters was an active founding member. He was a most successful teacher who soon acquired the devotion of his students. As an expert in the field of plant nematology he is irreplaceable and it will not be easy to find another parasitologist with such broad interests and so well able to inspire students. He will be greatly missed by his friends and colleagues and by his old students now scattered all over the world.

O. W. RICHARDS

A. E. Ingham

A. E. Ingham died suddenly on September 6, at the age of 67, while on holiday in Switzerland. He was reader in mathematical analysis in the University of Cambridge and a fellow of King's College.

Albert Edward Ingham was educated at Stafford Grammar School and Trinity College, Cambridge, which he entered as a Scholar in 1919. He was elected to a prize fellowship in 1922 at his first attempt. From 1926 to 1930 he was reader at the University of Leeds; he then returned to Cambridge as a university lecturer and a teaching fellow of King's College. He was made reader in 1953.

Ingham was a world authority on the theory of the distribution of the primes, and his Cambridge tract of 1932 (reprinted 1964) is still the standard account of the subject. To this difficult theory he made several notable contributions. I select for mention here the two which are probably best known to mathematicians generally.

(1) If p_n denotes the *n*th prime (so that $p_1=2$, $p_2=3$, and so on), one may ask how large the "gap" $p_{n+1}-p_n$ can be, in relation to p_n , when n is arbitrarily large. Hoheisel proved in 1930 that there is some exponent $\alpha < 1$ such that

$$p_{n+1} - p_n < p_n^a$$

 $p_{n+1} - p_n < p_n^a$ for all sufficiently large n. Ingham made a considerable advance in 1937 when he proved that the result holds with $\alpha = \S$, or indeed a little less. His method has still not been improved on.

(2) In 1919 Pólya put forward the conjecture that of the numbers $1, 2, \ldots, x$ there are always more with an odd total number of prime factors than with an even number, or at least as many. This has been verified up to 600,000. The conjecture would imply the truth of the Riemann hypothesis. In 1942 Ingham showed² that it would imply much more, namely, that the ordinates of the zeros of the ζ-function would be connected by infinitely many linear relations with integer coefficients. He proved a more specific result, involving only a finite number of the zeros, and so opened up the possibility of disproving the conjecture by computation. This was done in 1958 by the late C. B. Haselgrove (formerly a research student of Ingham), who showed further3 that the conjecture fails for some x less than e^{832} . Ingham's method is not limited to the investigation of Pólya's conjecture and is one of great generality.

Ingham made many other advances towards the solution of difficult problems in the analytic theory of numbers, but his work was not confined to this field; in fact, about half of his papers are on questions of analysis which have no direct relevance to the theory of numbers. He had a complete mastery of many difficult and delicate aspects of analysis, and in particular he added greatly to our understanding of Tauberian theorems4.

For a man of his standing, Ingham published relatively little: some thirty papers in addition to the tract. One has the impression from his papers that before publishing he had to satisfy himself that everything that could be relevant to his topic had been fully taken into account. When he did publish, every word and symbol was the subject of serious consideration, and the malpractices of editors and printers in changing what he had written were a source of much annoyance to him.

Ingham's lectures were always a pleasure to listen to, as many generations of students can testify. thought must have been devoted to their substance and to their presentation. Examining was another duty which he took very seriously; he retained throughout his life an interest in all branches of mathematics, and was often able to point out errors and obscurities in question s on subjects remote from his special field.

University News:

Birmingham

DR S. H. HOLLINGDALE, at present head of the Department of Mathematics in the Royal Aircraft Establishment, has been appointed director of computer services.

Manchester

DR F. H. SUMNER, at present senior lecturer in computer science, has been appointed professor of computing science in succession to Professor D. B. G. Edwards, who has been appointed to the ICT chair of computer engineering.

Massachusetts Institute of Technology

MR RICHARD G. MILLS has been appointed to the new position of director of information processing services, a post which is to provide co-ordination between all computer facilities in the institute.

Miami

DR R. G. BADER, head of the Division of Oceanography at the Hawaii Institute of Geophysics, University of Hawaii, has been appointed associate director of the University of Miami Institute of Marine Sciences.

Ulster

DR M. F. GRUNDON, at present reader in organic chemistry at the Queen's University of Belfast, has been appointed professor of chemistry.

University College of Townsville, Queensland

DR C. BURDON-JONES, senior lecturer in marine biology in the University College of North Wales and deputy director (marine biology) of the Marine Science Laboratories, Menai Bridge, Anglesey, has been appointed to the chair of marine biology.

Appointments

DR. JOHN M. HILL has been appointed chairman of the United Kingdom Atomic Energy Authority. Dr. Hill is at present member for production of the authority, with direct responsibility for the authority's Production Group. He succeeds Lord Penney, who is retiring in order to take up the rectorship of Imperial College.

MR M. V. TRACEY, at present leader of the CSIRO Wheat Research Unit, has been appointed chief of the CSIRO Division of Food Preservation, in succession to Dr J. R. Vickery.

DR RONALD S. PAUL has been appointed deputy director of Battelle-Northwest.

MR T. A. MANGELSDORF, a retired oil company executive from New Kent, Virginia, Dr C. G. Hurst, jun., a speech and hearing expert from Washington, DC, and Dr J. E. Harris, an ophthalmologist and university professor from Minneapolis, have been appointed to serve four-year terms on the US National Advisory Neurological Diseases and Blindness Council.

Meetings

SIXTH International Congress of Allergology, November 5-11, Montreal (Dr Samuel O. Freedman, Chairman, Organizing Committee, VI International Congress of Allergology, 1390 Sherbrooke Street West, Montreal 25).

GLOBAL Impacts of Applied Microbiology, November 6-11, Addis Ababa (Dr Aklilu Lemma, Dean, Faculty of Science, Haile Selassie I University, P.O. Box 1176, Addis Ababa, Ethiopia).

Engineer in Management, November 10-12, Scarborough (Mr B. Taylor, c/o Greenwood and Batley, Ltd., Armley Road, Leeds 12).

ERRATUM. Throughout the communication "In vitro Increase in Virus Infectivity", by C. E. Yarwood (page 269 of this issue), potassium sulphate should read potassium sulphite.

ERRATUM. In the communication "Late Pliocene-Pleistocene Stratigraphy in Deep Sea Cores from the South-central North Atlantic", by W. A. Berggren, J. D. Phillips, A. Bertels and D. Wall (page 253 of this issue), reference 14 should be inserted at the end of the third paragraph.

CORRIGENDUM. In the communication "Possible Instability in the Self-closure Phenomenon in Gravitational Collapse" by W. Israel (Nature, 216, 148; 1967), equation (3) should read

$$\lambda = -\frac{1}{2} \int_{-m}^{+m} (R^2 - 2 Rx \cos \theta + x^2)^{-\frac{1}{2}} dx \qquad (3)$$

CORRESPONDENCE

Pink Spots Galore

SIR,—I am replying to a recent comment entitled "Pink Spots Galore", which is a discussion of studies initiated in my laboratory. As a result of those studies, we reported, in 1962, that 3,4-dimethoxyphenethylamine (DMPEA) is a constituent of urine from schizophrenic patients^{2,3}. The writer states that "hats were thrown in the air" when these findings were reported, but that they have now been contradicted by the study of Boulton et al.4. In point of fact, I believe that reference to our publications will demonstrate that we have made a deliberate, and rather successful, attempt to prevent undue optimism or elation in regard to our work. It has been our attitude from the outset that these findings, while of considerable interest, may or may not be relevant to the aetiology and pathogenesis of schizophrenia. I do not feel that any additional findings made thus far, either positive or negative, have been sufficient to justify an alteration in this point of view.

The title of the editorial suggests that there are many compounds producing "pink spots". This is, of course, true and was pointed out by us in our first publication about this so-called "pink spot" test⁵. This test was developed by us to detect certain phenethylamines and developed by the course of the spot of the course of the spot of the course of the spot of the course of for nothing more. We went to great effort to identify the compound peculiar to schizophrenics (DMPEA) in order to avoid misunderstandings among various workers and to prevent ambiguous references to chromatographic "spots". We would therefore recommend strongly that the term "pink spot", which has come into use despite our efforts, be dropped and that each investigator should properly characterize and identify any compounds with which he is concerned.

It is my opinion that Boulton's conclusion that DMPEA is not present in urine of schizophrenic patients is incorrect, and that his inability to identify this material results from deficiencies in the methods that he used. However, not all divergent scientific findings can be reconciled at every point in time. It is my hope that each of the investigators involved in these studies will continue along his own lines, even though all of the results may not be consonant at the present time.

Sincerely.

ARNOLD J. FRIEDHOFF

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, October 23

INSTITUTION OF INDUSTRIAL SAFETY OFFICERS (in the Lecture Theatre' enstitution of Civil Engineers, Great George Street, London, SW1), at 2 p.m. -Mr. W. A. Wood: "The Application to Industry of Recent Advances in accident Prevention in the Mining Industry" (Alexander Redgrave Memorial

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Council Room of the Science Museum, Exhibition Road, London, SW7), at 5.30 p.m.—Mr. D. North: "Eclipses and Eclipse Computers in the Ptolemaic Tradition".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Londou, WC2), t 5.30 p.m.—Mr C. M. Van der Burgt: "Materials for Ultrasonic Delay Ines".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), t 5.30 p.m.—Professor A. Stratton: "Inertial Navigation".

UNIVERSITY COLLEGE LONDON (in the Botany Theatre, Gower Street, andon, WC1), at 5.30 p.m.—Dr R. J. Smeed: "Traffic Studies and Urban Congestion".*

University of London Institute of Education (in the Great Hall, King's College, Strand, London, WC2), at 5.30 p.m.—Professor G. H. Mantock: "The Idea of a Liberal Education".*

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, WC2), at 6.30 p.m.—Dr A. H. Cookson: Compressed Gas as High Voltage Insulation" (Chairman's Address).

Tuesday, October 24

UNIVERSITY COLLEGE LONDON (in the Anatomy Theatre, Gower Street, London, WC1), at 1.20 p.m.—Dr D. R. Harris: "Corn, Cucurbits and lultures in the New World—the Origins of American Agriculture".*

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), it 5.30 p.m.—Dr J. M. Linke, Mr I. F. MacDiarmid, Mr J. A. Taylor and dr D. A. Coles: "Correction of Linear Distortion in Wide Band Links for full-Channel Telephony and Waveform Transmission".

Institution of the Rubber Industry, London Section (at the Eccleston Totel, Victoria, London, SW1), at 5.30 p.m.—Mr R. C. Haines: "Golf-Balls—Old and New"; 7 p.m.—Mr A. Dibbo: "Role of Sulphur Donors in Compounds for High Temperatures".

RESEARCH DEFENCE SOCIETY (in the Physiology Lecture Theatre, University College London, Gower Street, London, WCI), at 5.30 p.m.—Proessor A. S. Parkes, CBE, FRS: "Animals in Captivity" (Thirty-sixth itephen Paget Memorial Lecture).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 5.30 p.m.—Professor R. L. Wain, FRS: "The Chemical Control of Plant Growth". (Lecture for Sixth Form Boys and Girls from Schools in London and the Home Countles. To be repeated on October 25, 31 and November 1.)

UNIVERSITY OF LONDON (at the Institute of Child Health, Guilford Street, London, WC1), at 5.30 p.m.—Dr J. M. Barnes: "Toxic Substances and the Nervous System". (Third of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "Cars for Cities".

Wednesday, October 25

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY (at Exhibition Road, London, SW7), from 2.30 p.m. to 7.30 p.m.—The work and new buildings of the City and Guilds College will be on view: Aeronautics, Chemical Engineering and Chemical Technology, Civil Engineering, Electrical Engineering, Mechanical Engineering, Centre for Computing and Automation.

INSTITUTE OF NAVIGATION (at the Royal Geographical Society, 1 Kensington Gore, London, SW7), at 5 p.m.—Annual General Meeting, followed by 'Rear Admiral Sir Edmund Irving, KBE, CB: "The Work of the Institute" (Presidential Address).

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr E. C. Rippon: "Power Plant for the 1970's" (Chairman's Inaugural Address).

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT IERE/IEE COMPUTER GROUPS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, WC1), at 6 p.m.—Dr G. Wooldridge and Mr T. J. Stakemire: "A Survey of Digital Data Display Systems".

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Mr H. G. Conway, CBE: "Engineering on the Air".

PLASTICS INSTITUTE, BUILDING SUBCOMMITTER (at the Building Centre, 26 Store Street, London, WC1), at 6 p.m.—Meeting on "Plastics in Internal Lighting".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (joint meeting with the Royal Society of Health—Food and Nutrition Section, at 14 Belgrave Square, London, SWI), at 6.15 p.m.—Dr A. G. Kitchell and Dr A. R. Hobbs: "Psychrophilic Bacteria in Foods".

SOCIETY FOR ANALYTICAL CHEMISTRY, MICROCHEMICAL METHODS GROUP (at "The Feathers", Tudor Street, London, EC4), at 6.30 p.m.—Discussion Meeting on "The Quantitative Analysis of mgm-Samples of Metals and Alloys".

Thursday, October 26

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 2.30 p.m.—Professor Hermann Bondi, FRS: "Relativity and Cosmology" (Civil Service

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W1), at 5 p.m.—Professor A. L. Takhtajan (USSR): "Classification and Phylogeny, with special reference to the Flowering Plants".

University of London (at the Institute of Child Health, Guilford Street. London, WCI), at 5.30 p.m.—Dr D. B. Hope: "Storage of Polypeptide Hormones". (Fourth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, WC1), at 5.30 p.m. - Dr S. Keiser-Nielson: "Forensic Dental Work: Cases and Comments".*

Friday, October 27

ROYAL INSTITUTION, PHOTOCHEMISTRY DISCUSSION GROUP (at 21 Albemarle Street, London, W1), at 1 p.m.—Dr. E. Reiser: "Photolysis of Aromatic Azides".

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London. SW1), at 6 p.m.—Discussion Meeting on "How Can Mechanization Reduce the Costs of Distributing Documents in Office Blocks?"

ROYAL INSTITUTION (at 21 Albemarie Street, London, W1), at 9 p.m.—Sir Paul Chambers, KBE: "Controlling an International Chemical Group".

Saturday, October 28

ASSOCIATION OF CLINICAL BIOCHEMISTS, SOUTHERN REGION (at the National Hospital, Queen Square, London, WC1), at 10 a.m.—Symposium on "Chemical Pathology in Relation to Neuropathology".

Monday, October 30

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr D. L. Thomas and Mr E. P. G. Wright: "The Impact of the C.C.I.T.T. No. 6 Signalling System on Telecommunications".

ROYAL INSTITUTION (at 21 Albemarle Street, London, Wi), at 5,30 p.n..-Mr Arthur T. Gill: "Faraday and Photography".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, WC1), at 5.30 p.m.—Dr N. A. Mitchison: "Control of the Immune Response".*

University of London Institute of Education (in the Great Hall. King's College, Strand, London, WC2), at 5.30 p.m.—Professor A. V. Judges: "The Idea of Equality in Education".*

INSTITUTION OF MECHANICAL ENGINEERS, PROCESS ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "The Implications of Going Metric".

Monday, October 30-Wednesday, November I

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2) — Conference on "Metering and Apparatus for Modern Electricity Supply Tariffs".

Monday, October 33-Thursday, November 2

INSTITUTE OF WELDING (at 54 Princes Gate, Exhibition Road, London, SW7)—Autumn Meeting on "Welding in Non-Ferritic Materials".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN THE BIOBNGINEERING UNIT IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C1 (October 28).

TENFORARY LECTURER/SENIOR LECTURER (graduate with a good honours degree or Dip. Tech. or equivalent in mathematics) in Mathematics at Britannia Boyal Naval College, Dartmouth, Devonshire—Ministry of Defence, Navy Department CEI(N) 368, Old War Office Building, London. SW1 (October 30).

LECTURER OF SENIOR LECTURER IN PATHOLOGY—The Registrar and Secretary, The University, Leeds, 2 (October 31).

RESEARCH ASSISTANT (with a degree, preferably in mathematics and preferably some knowledge of computer programming) in the School of Mathematics, to collaborate with Professor P. H. Roberts in research in theoretical hydrodynamics—The Registrar, The University, Newcastle upon Tyne, 2 (October 31).

SENIOR LECTURER IN PHARMAGEUTICALS; a SENIOR LECTURER IN PHARMACOLOGY—The Clerk to the Council, The School of Pharmacy (University of London), 29:38 Brunswick Square, London, WCI (October 31).

TECHNICIAN IN THE LOW-SPEED WIND TUNNEL LABORATORY, to be responsible for the maintenance of the wind tunnel and maintenance and construction of electronic and other measuring equipment—The Secretary. University of Edinburgh, Old College, South Bridge, Edinburgh, quoting Ref. No. NP[7]10/67 (October 31).

LECTURER (preferably with a Ph.D. degree, but those with a good first degree and relevant industrial experience will be considered) in the Micro-Biology Section of the Department of Applied Min and Robinstown, South Africa—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (South Africa—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (South Africa—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (South Africa—The Association

character) in the Basser Computing Department, School of Physics, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (Australia and London, November 20).

Chair of Prisical Chemistry—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh, 8 (November 30).

Chair of Prisical Chemistry—The Registrar, The University, Newcastle upon Tyne, 1 (November 30).

Fellow and a Sanior Fellow in Social Anthropology and Sociology at the Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (Australia and London, November 30).

Chairs (2) of Mathematics at the University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (Australia and London, December 1).

Assistant Experimental Officer (preferably with a degree or equivalent qualifications) to work on embryonic growth and differentiation in cell and organ culture—The Secretary, Poultry Research Centre, West Mains Road, Edinburgh, 9.

Grade B Assistant Lecturer in Biological Sciences—The Principal, Medway and Maidstone College of Technology, Horsted, Maidstone Road, Chatham, Kent.

Physioist (with a good honours degree in physics) to carry out radiation

GRADE IS ASSISTANT LECULULAR IN DIGINAL STATES AND MEDIAN AND MEDI

Editorial and Publishing Offices: MACMILLAN (JOURNALS) LIMITED, 4 LITTLE ESSEX STREET, LONDON, W.C.2-Telephone Number: 01-836 6633. Telegrams: Phusis London, W.C.2.

Subscription Department: MACMILLAN (JOURNALS) LIMITED, BRUNEL ROAD, BASINGSTOKE, HAMPSHIRE Telephone Number: Basingstoke 5431

Advertisements only should be addressed to: T. G. SCOTT & SON, LIMITED, 1 CLEMENTS INN, LONDON, W.C.2.

Telephone Number: 01-405 4743

HOW TO BUY NATURE Volumes start in January, April, July and October but subscriptions may begin with any issue.

The direct postal price per subscription for one or two copies of NATURE each week is:

YFAR 1967

*12 MONTHS (52 issues and 4 indexes)**£14.0.0** each Great Britain and Eire.....

YEAR 1968

*12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire.....£14.0.0 .each United States of America. (by air freight). \$48 each
Canada. (by air freight). \$52 each
Elsewhere overseas by surface mail. £14.0.0 each

(Charge for delivery by air mail on application.) *Shorter periods pro rata. (Minimum three months.)

MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

12 MONTHS (52 issues and 4 indexes)

Number of Copies	G.B. &	U.S.A.	Canada	Elsewhere
	Eire	(by air	r freight)	(surface mail)
3–5 6–11 12 or more	Each £13.10.0 £12.15.0 £12.0.0	Each \$42 \$40 \$38	Each \$46.00 \$43.60 \$41.70	Each £13.10.0 £12.15.0 £12.0.0

12 MONTHS (52 issues and 4 indexes)

Number of Copies	, G.B. &	U.S.A.	Canada	Elsewhere
	Eire	(by air	freight)	(surface mail)
3–5 6–11 12 or more	Each £13.10.0 £12.15.0 £12.0.0	Each \$46.50 \$44.50 \$42.50	Each \$50.50 \$48.30 \$46.00	Eech £13.10.0 £12.15.0 £12.0.0

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

Any 1968 portion of subscriptions now ordered will be charged at the 1968 price.

NATURE Volume 216 OCTOBER 28, 1967

All Planners Now

THE second report of the Council for Scientific Policy (see page 322) is more cautious than the first. The passage of time seems to have worn down a good many potentially rough edges. When the council was first appointed the best part of three years ago, it seemed adventurous and open-minded, ready to put the world, or at least a part of it, to rights. The first report seventeen months ago bristled here and there with signs of willingness to rush to the defence of the scientific community against all kinds of threats and impediments, from parsimony at the Treasury to indifference among the administrators. Now, however, the council seems more firmly under the influence of conventional doctrines. It seems a little over-anxious not to rock the boat—not even the other fellow's. On the face of things, at least, it seems to be suffering from an excess of statesmanship of the kind which has afflicted the Science Research Council in the recent past (see Nature, 215, 1215; 1967). And the council is still asking what its function should be. This may be a bad sign, but it is a good question.

It would be wrong not to give the council credit for several important innovations. Soon after taking office, the council embarked on a number of special studies of matters affecting the relationship between science and the community, and many of these have now brought valuable benefits. The Dainton Committee seems, for example, to have done valuable work, and its final report should have an important influence in the potentially fruitful negotiations on which the schools and the universities are soon to be engaged if only the Department of Education and Science can publish it in time. The interim report of the Swann Committee was a healthy shot across the bows even if it has sometimes been quoted in evidence by those who wish mistakenly to prove that technology is both distinct from and in some sense morally superior to science. But in the long run the influence of the Jones Committee on the brain drain could be more lasting and more profound, for that document has provided a splendid analysis of the causes not merely of emigration but of the discontents of an industrial society as well. For these good works, and for others yet to come, the council deserves full credit. It has done this part of its job more thoroughly than it has ever been done before.

The council can also claim credit for the eloquent justification in its most recent report of scientific research in an industrial community. It is too easy to overlook the ways in which seemingly academic work can often, but unpredictably, bring great benefits of all kinds. It is true, of course, that some societies are able to sustain quite rapid economic growth without

spending large sums of money on scientific research, but this is probably a transient phenomenon. For countries like Britain, to turn back could easily bring disaster of some kind, cultural if not economic. It is particularly welcome that the council insists on the difficulty of deciding in advance which kinds of academic research are likely to be more profitable than others. There may be some who ask why the council did not add that research is in any case a necessary part of teaching, so that some of what is at present spent in the universities should be counted as education money; the council could certainly have done more to construct objective yardsticks with which to determine the proper scale of various kinds of expenditure. Should there not, for example, be some kind of link between the postgraduate population and the cost of university research? The working party under Sir Harrie Massey which is now studying the support of scientific research in the universities may yet have useful suggestions to make on matters like these. With luck, the council's exhortation on the value of research should help to bridge the gap.

The council is also to be commended for its attachment to planning, even if interpretations of what this means are sometimes unimaginative. The argument is that budgets which are determined from year to year are bound to mean that valuable resources are wasted, and that big projects always seem impossibly expensive. No doubt the nasty summer which the National Science Foundation has spent before the congressional committees in Washington is another reason why the council and its dependent research councils welcome the promises which seem to have been won about the scale on which scientific research will be supported in the three years ahead. Better a bird in the bush than two on the wing is what they are no doubt saying to themselves. At the same time there is probably a good case for thinking that academic research should not come to too much harm if the money spent on it increases (in real terms) by 9 per cent a year for the next decade or so. This would imply that the annual expenditure of the research councils would increase from £80 million now to just over £200 million at the end of the seventies, by which time it will be a great surprise or a great scandal if the cost of higher education as a whole does not exceed £1,000 million every year. Obviously the council's wishes are not outrageously ambitious. For the time being, it has probably struck as good a bargain as any to be had.

So why should sensible men complain? Everything hangs on the question of what the Council for Scientific Policy is meant to do. There is an impassioned

sentence in the new report which says that "if we could summarize the purpose for our existence in a single sentence, it would be to understand the scientific environment, to advise on its preservation in current difficult conditions, and to convince both scientific and lay opinion that the nation wills its proper support". This implies more than mere budget-making. Taken at its own valuation, the council should be a public influence, as much concerned to see that reasons for its recommendations are widely understood as to ensure that its recommendations are sensible. This, no doubt, is what Mr Patrick Gordon Walker, the Secretary of State for Education and Science, had in mind when he spoke on Tuesday of the way in which the council should engage in a continuing dialogue with the scientific community. Yet there seems a serious danger of the council lapsing into the secretive and passive ways of those who equate public discussion with unwelcome criticism.

The council's justification of the growth rates agreed for the years immediately ahead is one example of this unhealthy tendency. Is the 10 per cent increase for the year ahead intended as a recommendation or is it merely the best that the council was able to negotiate with the Government? And how much was the council influenced by its espousal of the fashionable but potentially misleading view that industry will benefit if life is made less comfortable for those who work in universities? The council's latest report would have been more valuable if it had been more explicit on these points. It would then, for example, have been easier to understand why the Science Research Council was the other day lamenting the way in which desirable projects have had to be postponed for lack of money. It would then also have been easier for the scientific community in Britain to have participated in the kind of dialogue for which Mr Gordon Walker is hoping.

Reticence about the exact status of the forward estimates of growth is nothing like as damaging as the decision not for the time being to publish the full report of the committee on the 300 GeV accelerator. By keeping it secret, the council and the Government between them will only create the impression that there is something to be hidden. No doubt the objective is somehow to save the Government from embarrassment if it should eventually decide not to accept every detail of the council's advice on the 300 GeV machine. But would this really matter? Governments are always repudiating or ignoring their advisers, sometimes with good reason. The council's advice on the 300 GeV machine might well be overridden by wider financial or political considerations, for example. Its function as a sounding board for public discussion of the principles on which science policy should be determined would be enormously strengthened if on this, as on other issues, it had been able to make a greater show of openness and independence.

The habit of public reticence about matters of public importance is not, of course, a fault possessed only by the Council for Scientific Policy. It runs through

the whole of public life in Britain, no doubt because of the way in which it is assumed that the Civil Service is answerable not to the public but to the ministers in the Government. The results, nevertheless, are frequently absurd. The existence of the committee which has been examining the 300 GeV project was something of a secret until the publication of the second report earlier this week. In other fields, reticence is not merely an impediment to public understanding but positively harmful as well. Why, for example, should those who are in charge of the sensible scheme for sharing expensive apparatus among colleges of the University of London (see page 320) be unwilling to explain how the system operates? Why, for that matter, should Dr Husband be able to explain (see page 319) to the conference of radio-telescope designers in Massachusetts last week a good deal about the design conception of the radio-telescope he may yet be building for the Science Research Council when the council itself says that the design must be confidential for the time being? Reticence on simple matters like these can serve no useful purpose and yet is not merely an irritation but a sign of how far there is to go before the relationship between the bodies which administer science in Britain and the scientists for whom they do so is anything like as open as it should be.

The advice which the council has actually given on the 300 GeV machine also leaves a great deal to be desired. It is fair, of course, to make reservations about the damage that would be done to the pattern of expenditure in Britain if the costs of the 300 GeV machine should increase dramatically, and the council is also on sure ground in saying that a decision to contribute to the 300 GeV machine sets a lower limit to the pace at which the budget for civil science as a whole must continue to increase. On the assumption that the conditions will be met, however, the council could have given a more straightforward statement of whether it thinks the 300 GeV machine is desirable or not. Does the council, for example, consider that a nuclear physics budget increasing at 7 per cent a year is reasonable? And if it does, should not the council also have given the project to build the machine more enthusiastic backing?

The most serious cause of disappointment in the council's new report is, however, the way in which it seems not to have tackled a great many important What, for example, is happening to the National Library for Science and Invention? Is it really safe to think that the scale on which computers are being employed in universities is sufficient to meet the real needs? Although the report of the Flowers Committee on university computers has had a beneficial influence, complaints abound of shortage of facilities and there is in any case a great deal to be done before undergraduates at universities have access to up to date machines. The relationship between Government establishments and universities is also urgently in need of close attention—the council's first attack on this important problem turned out to be an exceedingly damp squib. And then, of course, there is the

whole question of the development of higher education in the years ahead. Will the new polytechnics carry out research on a substantial scale, and, if so, who will pay for it? What about the need for more post-graduate education? It is a long time now since the Robbins Commission raised this issue, yet very little has been done. In these and many other ways, the

council could become much more vigorous and constructive. It could also in the process help not merely to awaken the interest of the scientific community in its work but also to extend its influence on the development of scientific research in Britain. That, so far, has been a good influence. The need now is that there should be more of it.

Assessing the AGR

IT has never been easy to feel optimistic about the export prospects of the British nuclear power consortia, committed as they are to the advanced gas cooled reactor. It is clear for a start that the AGR is an expensive piece of equipment compared with an American boiling water reactor. But in the past it has been possible to hope that the greater capital cost of the AGR could be outweighed by its high thermal efficiency and fuel economy. This notion has come under increasing attack since 1965, when an AGR won the contract for Dungeness B power station against competition from a boiling water reactor. clear from the latest annual report of the Kjeller Laboratory of the Norwegian Institutt for Atomenergi that Norwegian companies, at least, are unlikely to be convinced by it.

Since the beginning of 1966, the institute has collaborated with the Norwegian firm Norsk Hydro on a study of different reactor systems for a 500 MW nuclear power station. A preliminary costing study shows that the AGR is the most expensive type of all. For an AGR of 600 MW(e) the total plant cost would be £43.5 million, excluding initial fuel charges. (In Britain a similar station would cost more, the report says, because of "the very special requirements of the Central Electricity Generating Board".) Generating costs would be 0.41 pence/KWh. For a boiling water reactor the same size, initial costs would be £34.6 million, and generating costs would be 0.393 pence/ The other types studied, which included the pressurized water reactor and the heavy water pressure tube reactor, fell in between these two extremes. The fast reactor, the report suggests, would be the cheapest of all, supplying electricity at a cost of 0.264 pence/ KWh, but the figures are admittedly speculative.

In the larger sizes, the gap between the AGR and the BWR narrows slightly; for a 1,000 MW station, generating costs for the AGR would be 0.38 pence/KWh and for the BWR 0.367 pence/KWh. As a result of this study, the institute has decided to carry out a more extensive study to compare the light water boiling reactor with the heavy water boiling reactor.

The UKAEA is inclined to doubt the validity of the assessments. The figures for the AGR, which the AEA itself supplied to the institute, are accurate, but the BWR costs were taken from a catalogue issued in 1964 by the General Electric Company (US). Since then, the AEA says, GE costs are up by 20–30 per cent; an adjustment of this order would bring the figures into line with the Dungeness B assessment. In any case, although calculations of this sort can give a general feeling for the costs, they are not accurate enough for final decisions to be taken, and the decision to go ahead with the BWR and the heavy water boiling reactor is probably "an unreasonable deduction from the strength of the exercise". Only the discipline of tendering can

really establish costs, the AEA believes; a conclusion shared by the delegates at a recent IAEA symposium in London.

Rescuing the Dragon

DURING 1967, the Dragon reactor at Winfrith Heath became the first system to demonstrate the feasibility of high temperature reactors. In the process, it also became the first system in Britain to demonstrate the cliff-hanging financial arrangements of Euratom. The Dragon is a collaborative reactor supported by the countries of OECD; most of the cost falls on the United Kingdom and the Euratom countries. During 1967 Euratom was unable to agree to an extension of the Dragon programme into 1970, and as a result the UK declared itself willing to bail out Dragon for the whole of 1968 if necessary, to give Euratom more time. Euratom now has two decisions to make; the immediate one is to decide whether to accept the British offer. If Euratom refuses, the UK (together with the other OECD countries not in Euratom) will go ahead for at least one year, and take over the whole project. If Euratom accepts the interim British offer, it will then have to decide, some time next autumn, whether to go on into 1969. If the answer then is yes, Euratom will repay to the UK the share of the 1968 costs: if it is no, then the UK will take full charge of the project. The UK will either get its money back or be left with a project which is almost completely paid for, and is now producing useful information. The UKAEA believes it has a very good deal.

The reactor has operated well, despite a leak which developed in the heat exchangers, allowing helium to leak from the primary to the secondary circuit. The fuel charge developed for the reactor, consisting of particles of thorium and enriched uranium carbides coated with layers of silicon carbide and pyrolytic carbon and contained inside graphite tubes, has worked perfectly, the report says. The fuel reached a temperature of 1,250° C and a burn-up of 25 per cent of the uranium-235. A second fuel charge has been developed, with improved particle coatings and graphite, and it has been possible to do without the arrangements for purging the fission products which were incorporated in the first fuel charge. During the year the work of assessment on a full scale power station using the Dragon concept has been continued. One design, called the feed and breed concept, calls for a mixture The breed fuel contains fissile uranium-235 and fertile thorium-232 in such proportions that the ²³³U which is bred replaces the original ²³⁵U at the same rate as it is burned. To maintain the reaction, since breed fuel cannot be made critical, part of the core contains highly enriched uranium, the feed

Hard Words about Pollution

DR E. F. SCHUMACHER, economic adviser to the Coal Board, was brave enough last week to attack the safety standards in nuclear power stations. In a speech to the conference of the National Society for Clean Air (Nature, 216, 219; 1967) Dr Schumacher claimed that nuclear power stations would gradually contaminate the environment, by "silently leaking radioactivity into the ground". The increasing use of nuclear fuel would add to the dangers of accidents in transport, and what would be done with nuclear power stations when they came to the end of their active lives? Dr Schumacher pictured them standing idle all over the country as mute witnesses to the folly of allowing economic criteria to dictate policy. No insurance company, he added, would take on third party risks for nuclear power stations.

The spokesmen for the Ministry of Power and the Electricity Board responded with the alacrity born of long experience of the Coal Board. Mr Peter Williamson, for the CEGB, managed to get his reply in first, by responding to Dr Schumacher's speech at the conference. Reactors once out of use would be sealed up and covered up with a mound of earth, he said, and would be no danger. Accident-proof containers have been designed for the transport of dangerous materials, and insurance companies did accept the third party risks for nuclear stations. The Ministry of Power was slower to react, but no less decisive. Dr Schumacher's statements, the ministry said, "are so inaccurate that they cannot be regarded as a serious contribution to any discussion of the subject". External radiation from power stations, it added, is virtually non-existent.

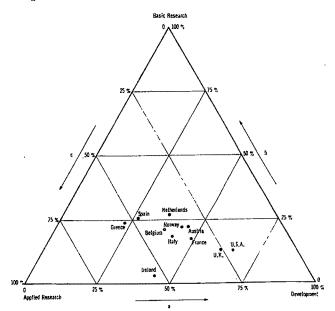

Later, Dr Schumacher claimed that his remarks had been misinterpreted. He has no criticism of the way in which dangerous materials are handled at the moment, and regrets that certain points used to illustrate the theme of his address should have been taken as an attack on standards of public safety. The caution Dr Schumacher made was against too much emphasis on economics. Too often the cheapest production methods for commodities are used without enough consideration of the human factors involved. A massive increase in nuclear power installations might not be matched by a greater knowledge of how to protect man from dangerous radiation.

Know your loneses

THE amount a country spends on research and development is probably the most confusing index of economic performance ever devised. Even so, British ministers will doubtless feel encouraged when they read a recent report prepared by the Organisation for Economic Co-operation and Development (The Overall Level and Structures of R and D Efforts in OECD Member Countries, OECD, 9s.). The fact that Britain spends far more than other European countries on research is likely to be regarded by British supporters as a further reason why Britain should be admitted to the Common Market. But it would be equally easy to say that a large research budget, combined with a stagnant economy, merely emphasizes how loth Britain is to

The United States, of course, leads the field by a very substantial margin. It spends more both in real

terms-more than \$21,000 million-and as a proportion of gross national product—3.4 per cent. Great Britain spends \$2,160 million, 2.3 per cent of the GNP, while France and Germany manage \$1,299 million (1.6 per cent) and \$1,436 million (1.4 per cent) respectively. Other countries of the EEC trail well down the field; Italy spends only 0.6 per cent of the GNP on research and development. The Netherlands, on the other hand, spends 1.9 per cent and Sweden 1.4 per cent.

This diagram, after the style familiar to metallurgists and physical chemists, shows the amounts spent by countries on basic research, applied research and development.

The report does nothing to encourage illusions of the value of these figures. "International comparisons of GNP percentages are not good yardsticks for science planning. Such an evaluation can be made only in the light of the research and development aims a country sets itself, some of which are more costly to realize than others." For this reason the report makes a useful analysis of the proportions spent on different areas of research. About two-thirds of the expenditure in the United States, for instance, is devoted to nuclear, space and defence research and development. France spends 45 per cent of her total in these three fields, and Britain just under 40 per cent. According to the figures, Japan spends nothing at all on these activities.

The United States employs as many qualified scientists, engineers and technicians as the rest of the OECD countries put together. A full-time equivalent of 700,000 qualified people is estimated for the United

RELATIVE EXPENDITURES ON RESEARCH AND DEVELOPMENT IN SELECTED INDUSTRIES

	(US equ	als 1,000)		
	Air- craft	Elec- trical	Chemical	Manu- facturing industry
United States	1,000	1,000	1,000	1,000
United Kingdom	76	103	112	96
Germany		94	175	62
France	28	63	80	44
Japan		57	93	41
Italy		6	29	11

States, while Japan comes second, with 187,000 qualified people. The formula used assesses people in terms of full-time equivalent, to take account of those who spend only a proportion of their time on research. The United Kingdom has 160,000, West Germany 105,000 and France 85,000.

The report also compares the expenditures in various industries with that in the United States (see Table), and this comparison is even more striking; if the whole of Europe were united overnight, the research and development expenditures in the aircraft, electrical and chemical industries would amount to less than half the totals in the United States.

American Technology

How should applied research be supported? The National Academy of Sciences in the United States, having dealt with basic research in a report called Basic Research and National Goals, has now turned its attention to applied science. The result, Applied Science and Technological Progress, is a free-ranging collection of essays tied—sometimes rather tenuously—to the basic theme. The report, prepared for the Committee on Science and Astronautics of the House of Representatives, also includes an introduction which bravely attempts to find common themes in the essays and to draw conclusions.

The mission-oriented laboratory, most members of the panel agree, is a happy invention for applied science. One of the recurrent themes is the difficulty of maintaining the vitality and spirit of these laboratories; Dr Alvin Weinberg, director of Oak Ridge, is daring enough to suggest that they should be turned over to the solution of social problems—pollution, race and crime. What, he asks, is to become of the fine laboratories of NASA after the Apollo mission has been completed? Agency laboratories have a way of becoming obsolete, especially when the agency is organized around a technology. This is recognized in the introduction to the report, as is the difficulty of changing the direction of a laboratory—this preoccupation echoes the problems of the United Kingdom Atomic Energy Authority.

The university, on the other hand, is not a good place for applied research, although the panel sees some hope that the advent of the computer will allow university workers to engage in the problems of real life, at least by proxy. Close association between universities and applied research laboratories is important, and there is at least an undercurrent of fear that the increasing influence of university attitudes in American life is causing people to regard applied science as a second-class activity—and this in a country where, the introduction rightly points out, industrial research has been a magnificent triumph.

At least two of the essays give fascinating blow-byblow accounts of these triumphs. Donald Frey and Jacob Goldman from the Ford Motor Company discuss innovations ranging from high pressure metal forming to micro-electronics, and C. Guy Suits and Arthur Bueche from General Electric do the same for their own company. The case studies show that there are few common factors in the process of innovation except determination; some successes are the result of deliberate investigation but others, equally important, are a mixture of luck and good observation. This has been said often enough, but rarely demonstrated as clearly as Suits and Bueche manage to do. discovery that fission tracks in mica can be etched out to form tiny holes, for example, was originally intended as a filter for blood, but has been applied to a great variety of scientific and commercial uses, from nuclear physics to the age determination of tektites. Faced with this diversity, it is hardly surprising that the panel was unable to establish hard and fast rules for applied science, although some general principles did emerge. Secrecy in applied science is a bad thing, and therefore the patents system must be preserved, for without it greater secrecy would be inevitable. Personal mobility is also important, and may, the panel considers, be where the United States differs from less successful countries. The technical entrepreneur, the man whose enthusiasm for a project may often exceed his technical understanding, is frequently a vital element in successful innovation. Finally, the panel has a good word to say for technological forecasting, but adds a caution-forecasting can do more harm than good if its results are treated as more than rough first approximations.

Who Builds What?

THE construction of a 400 foot radio-telescope somewhere in Britain seems to have been carried one step forward in the past few days with the decision of the Science Research Council to negotiate a contract for design and construction with the consulting engineering firm Husband and Company. The principal of the firm, Dr E. C. Husband, has been deeply engaged in the design of radio-telescopes since his involvement with the 250 foot instrument which has been operating at Jodrell Bank since 1957. The decision to negotiate with Husband and Co. rather than with the other firms which have submitted proposals has been taken the recommendation of the Atomic Energy Authority, which has been acting as an agent for the Science Research Council during the feasibility study now completed. Some confusion seems to have been caused by the way in which Dr Husband let it be known, at a conference on the design of radio-telescopes at the Massachusetts Institute of Technology last week. At that stage it seems that the decision had not been communicated to the unsuccessful firms.

The council's immediate commitment is to the detailed design of the telescope, on which work will now begin. In the first half of 1968, it should be possible for the council to make a final decision to go ahead with construction of the telescope. By then it should also be known just what the instrument will cost. With luck, the council hopes to build the new instrument for a good deal less than £5 million. The intention is that the dish should be constructed accurately enough for the whole of its area to be usable at the wavelength of the 21 cm hydrogen transition, and at the slightly shorter wavelengths now being used increasingly by radio-astronomers. The choice of Dr Husband's company implies that the new dish will be supported on an open steel beam itself held above the ground by vertical legs. Husband says that this type of design is preferable to that in which the dish is supported at the centre by a single column because of the more sensitive control of position which is then possible.

Research Service

THE University of London Intercollegiate Research Service was first discussed about ten years ago. After nearly three years of hard work by a committee under Professor W. Klyne, the final scheme has been announced, with details of the allocation of funds. Altogether the Science Research Council is providing £170,000 to set in motion the service "for chemistry and related sciences".

Sophisticated scientific instruments are now so expensive that it would be impracticable to install and maintain all types of instrument at every college. The intercollegiate research service has been designed so that research workers from colleges inside and outside the University of London can have access to all Seven colleges are housing and the instruments. running the machines, making about 50 per cent of the operating time available to outside departments. The general principle is that samples are submitted, probably by post, to the department in question. technician working with the machine makes the readings and the results are returned. Detailed arrangements may vary to make the best use of each type of machine.

The SRC grants have been awarded as follows: £14,560 for X-ray crystallography and £25,248 for laser Raman spectroscopy at Imperial College; £19,974 for Raman and long wavelength infrared spectroscopy at King's College; £26,925 for nuclear magnetic resonance spectrometry at Queen Elizabeth College: £23,519 for electron spin resonance spectrometry at Queen Mary College; £36,425 for mass spectrometry at the School of Pharmacy; £14,025 for mass spectrometry at University College; and £9,100 for optical rotatory dispersion and circular dichroism at Westfield College. Two-thirds of the machines are already installed.

A report was made to Dr G. Johns of the SRC in September on the machines in use, including some which have been operating for nearly a year. There seems to be no particular reason why an official announcement of the service should have been made at this stage in the proceedings, and there seems to be an ambivalent attitude to publicity amongst those involved with organization. Although parts of the service have been running smoothly since January, Professor Klyne is reluctant to describe the facilities in detail, possibly for fear of an influx of samples to be tested. grapevine has been working in the chemistry departments of the University of London, but physicists and biochemists who might be keen to use the new instruments have had no official information. individual colleges are anxious to help where they can, and, when time allowed, have run spectra for various industries. Professor B. C. L. Weedon, head of the University Board of Studies in Chemistry, thinks the service deserves publicity, especially in other universities which could well benefit from co-operative organizations of this kind. Professor Klyne's committee is hoping to produce a booklet in the near future, which will give instructions on how to send in samples, and the various facilities available.

New Role for BISRA

DOUBTS about the future of the British Iron and Steel Research Association (Nature, 214, 867; 1967) have

now been resolved. The Council of BISRA have accepted the offer by the British Steel Corporation to take over responsibility for finance and operation of BISRA from October 31, 1967, when the dissolution of the British Iron and Steel Federation takes place. BISRA will then become the central laboratory of the BSC, and will concern itself with problems common to more than one of the four groups of the corporation. At the same time, the research done by BISRA within an agreed scope will be made available to the private steel companies, now represented by the British Independent Steel Producers Association.

The future work of BISRA will probably break down into three broad categories. As well as the co-operative research programme which has to be agreed by a technical collaboration committee jointly appointed by the BSC and the private companies, there will be sponsored work-which will doubtless include work for the corporation and for the private companies—and there will be work which falls outside the co-operative programme and is therefore available only to the corporation. The association is out to disprove the notion that collaborative work is impossible if one group dominates the others in size—and, in this case, in nature. In effect, BISRA had little choice but to accept the corporation's offer, since the fourteen nationalized companies supply as much as 80 per cent of the association's income.

BISRA sees its work as the central laboratory of the corporation as being slightly different in emphasis from that carried out by the individual groups of the corporation. BISRA will concern itself with problems common to several groups, and to the general improvement of processes, plants and products. The group research departments are likely to be concerned with more immediate problems in the day to day running of the plant, and problems specific to the product manufactured by the group they represent.

Mental Health Research

PEOPLE with cheque books will be interested to learn that the Institute for Research into Mental Retardation is now registered as a charity. The institute, whose chairman is Lord Francis-Williams, was founded in April 1966 by the National Society for Mentally Handicapped Children which donated the first grant of £5,000. Its function is to co-ordinate research, to provide a centre of information and to promote collaboration between workers of various discplines. Eventually it hopes to attract support from all kinds of charities.

Although throughout the world a mentally retarded child is born every twenty seconds, the governors of the new institute are enthusiastic and optimistic. Dr D. Morris, vice-chairman of the institute and a practising paediatrician, suggests that prevention is possible in about half of the cases whose deficiency originates during the perinatal period. Five projects in primary prevention are already being sponsored by the institute, aided by a grant from the Wates Foundation. example, research workers are anxious to know what causes the well known extra chromosome (chromosome 21) in the cells of mongols and how this shows itself in the clinical symptoms. The incidence of mongolism increases with age of the mother and this could possibly be attributable to the ageing of ova. Another promising

line of work involves mosaics: some mongols have an extra chromosome in all of their cells, others in only a few. Although it is not feasible at present, if some mongols could be made into mosaics, their appearance and behaviour would resemble more closely those of a normal person. Other puzzling questions include the number and nature of genes carried by the extra chromosome.

Prevention apart, the institute aims to make life a lot better for the mentally retarded. Already it has been effectively demonstrated that after appropriate training mentally retarded individuals can be economically productive, not only in sheltered workshops but also in open employment. It is, however, both unfortunate and surprising that the information service provided by the institute is well financed, while the actual research work is dependent on charities and private donations.

More about Pollution

Most records of air pollution are from towns and industrial areas and there is much less information on background levels of pollution in agricultural districts. To remedy this state of affairs, the Agricultural Research Council has now compiled a comprehensive review of the literature on the effects of air pollution

on plants and soil.

The report describes a number of toxic elements and pollutants; how they originate and how they should be treated. The total emission of smoke in Britain, for example, has been declining for some years but reaches a higher concentration in winter. Deposited matter, including soot, tar, dust, grit and ash, is mainly derived from the combustion of solid fuels. So, too, is sulphur dioxide; in 1963, 68 per cent of sulphur dioxide came from burning coal, 7 per cent from coke and 25 per cent from oil. At Battersea and Bankside power stations in London, flue gases are washed with water from the Thames to which chalk has been added: this process removes 90 to 98 per cent of gases but it is costly, and more attention has been paid to dry processes in recent years. Fluorides are emitted by some brickworks and possibly by some potteries and cement kilns, but fluoride pollution is rarely reported in Britain now. It remains to be seen whether photochemical or oxidant smog, often referred to as Los Angeles smog, will be troublesome in Britain in future.

According to the review, the toxic effects of many pollutants vary with species and variety, with environmental conditions, with nutritional levels and with the stage of growth of the plant. Smoke and deposited matter have an adverse effect on photosynthesis by reducing the light intensity, blackening leaves and blocking stomata. Conifers are particularly sensitive to sulphur dioxide, which causes acute damage to leaves. In soils which have suffered heavy pollution for prolonged periods, oxidation and solution of the gas in rain water result in increased acidity and sulphate content of soil, with a corresponding reduction in calcium and other gases and reduced activity of micro-organisms. Fluorides, on the other hand, act as cumulative plant poisons and the consumption of such vegetation can cause fluorosis in cattle and sheep. Oxidant smog produces silvering and bronzing of the lower leaf surface, although it can cause physiological

disturbances and reduced growth in some species without producing any visible leaf symptoms.

Landing on Venus

from a Correspondent

THE drama at Jodrell Bank last week when the Soviet Union Venus 4 spacecraft reached the planet recalled the days of the early sputniks ten years ago.

Signals from Venus 4 were picked up at 0417 BST, some 40 minutes after Venus rose above the horizon. They were described as consistent with the signal strength recorded in July, with 2-tone telemetry similar to the Luniks' transmissions but speeded up four times. Besides recording, Jodrell was also measuring Doppler shift. At 0440 the distance of Venus 4 was estimated at 30,000 km and speed change at 30 cm per second per second. The received signal strength was 10^{-17} watt, assumed to be 1 watt transmitter power boosted to 200 watts effective power by the 2-metre directional antenna on the spacecraft.

It was estimated by the Jodrell team that if a Venus orbit or a main spacecraft soft landing was aimed for, the signal shift would slow between 0550 and 0530, the expected time of arrival at the surface. No such signal modifications occurred while the spacecraft continued to transmit and show enhanced frequency shift. At 0515 it was estimated to be 10,000 km from the surface. At 0538 05, the signals ceased, compatible with the probe ceasing to transmit at about 100 km from the surface.

As is now known, this was in fact the beginning of the main experiment, but further signals were not expected, and though the equipment continued to observe no recordings were made of the early part of the new transmissions. These began 15 seconds after the end of those from the main spacecraft. There was a hundred-fold drop in signal strength, compatible with the loss of the 2-metre high gain antenna, and the same telemetry as before was apparent but with many fewer data, as would be expected from the power reduction. The apparent stillness of the new transmissions led the Jodrell team to assume that the signals were coming from an ejected capsule actually resting on the planetary surface.

Some time later, it occurred to the Jodrell team as well as to some other commentators that the data had been transmitted in real time as the ejected capsule descended from 25 km to the surface of Venus in 90 minutes. Soviet sources gave 90 minutes as the period taken to descend and this exactly corresponds with the transmission registered at Jodrell Bank. The capsule transmission cut out sharply "as if on command" at 0714 BST. There has as yet been no conclusive evidence that the capsule did make a soft landing on the surface, or that its transmissions continued after touchdown, or that it directly measured surface conditions. It was certainly designed to do all these things-it had the same basic configuration as last year's first successful Soviet lunar soft landing by Lunik 9, with a weighted base to ensure it settled right side up. Indications are that this was not the main object of the experiment but a possible bonus. A sounding of entire Venus atmosphere from top to bottom which must have included very near-surface measurements makes a significant addition to planetary knowledge.

Planning Ahead

The second report of the Council for Scientific Policy raises questions of the problem of research in Britain.

THE principal centres of interest in the report of the Council for Scientific Policy, published on October 24 (Cmnd 3420, HMSO, 4s. 3d.), are the estimates of what will be spent by the four research councils between now and the financial year 1969-70 and the council's recommendations to the British Government about British participation in the building of the 300 GeV accelerator within CERN. On the first score, the council has agreed with the Government provisional figures for the two financial years ahead which represent annual increments of 10 and 9 per cent respectively. On the accelerator, the council has urged that the British Government should participate in paying for it on the assumption that the British contribution towards CERN is in future proportionately no greater than it has been in the past and provided that "assurances can be obtained that resources will be made available for science on a scale sufficient for both the 300 GeV machine as part of the nuclear physics programme and the proper development of other fields of science". The council comes near to specifying what it would consider a sufficient assurance with its estimate that the cost of other kinds of science than nuclear physics will grow at about 9 per cent per annum in real terms over the decade ahead.

Planning and the need for it is indeed the central theme of the council's report. As an earnest of its intentions, the council is already discussing with the research councils plans for expenditure in the financial years 1970-71 and 1971-72. Several benefits are expected to accrue from developments like these. For one thing, the council expects that the ability to make firm commitments will enable the research councils to make more efficient use of available re-The council's deliberations on the 300 GeV machine have plainly served as a telling object lesson of how the long time-scale on which large capital projects must be planned implies that other kinds of expenditure should also be determined in advance for a comparable interval of time. But there is more to be said than this. In the peroration to its report, the council emphasizes that long-term planning is the only way of creating confidence in the continuing development of science. "We believe that much of the problem of emigration of scientists can be dealt with by these means.

The council also acknowledges that the rapid growth of the budget for civil science in Britain since the war—from £6.6 million in 1945 to £295 million in 1967—implies that the council has the responsibility of justifying continuing growth. For one thing, the council points out that if science budgets are measured by the proportion of a nation's GNP devoted to them, the British performance may have been deteriorating by comparison with the United States in the past five years or so. British expenditure on research and development since 1961 has been static at 2.7 per cent of the GNP, but research and development in the United States has risen from 3.0 per cent of the GNP in 1961 to 3.2 per cent in 1964.

The council's chief justification of expenditure on scientific research is more philosophical than this, however. It argues against too rigorous an attempt to assess the potential value of particular programmes in basic research by estimating what measurable economic or humanitarian benefits might accrue. It points to the way in which work in electron physics has led to practical applications in electronics, and to the potential benefits which may come from recent developments in molecular biology. There is a passage in the report about the way in which medical research has brought "an immeasurable gain to humanity in terms of happiness and health", and numerical calculations of what this means in terms of more people at work and fewer people in hospital. In agricultural research, the council mentions the increase of agricultural output from British farms of 44 per cent in the decade from 1954 in terms which attribute some of this improvement to agricultural science, and the council also says, in a reference to the work of the Natural Environment Research Council, that "in no field more than the natural environment is the potential gain from applied research more spectacular or more neglected".

But this is only a part of the story. Basic research is the only assurance of a continuing flow of original discoveries "from which all other progress flows". The council considers that the way in which countries such as Japan have been able to make rapid progress in technology without spending as great a proportion of the GNP on research and development is proof of the need in Britain for closer relationships between industry and research. "We have seen no evidence that we must write off our long-term insurance for the future in order the better to exploit the already existing results of science".

As it happens, the council does not quote in this most recent report the argument which appeared a year ago that the pace of growth in scientific research would somehow have to be matched with the pace of growth in other sectors of the economy. also some evidence that the council has moderated its demands on the public purse by its recognition that there is a need to bring about a "reorientation of objectives towards the application of science for some of the ablest young men emerging from the universities". The estimates of what will be spent by the agencies under the control of the Council for Scientific Policy in the years ahead are shown in Table 1. Fluctuations from one year to another in the spending of individual research councils are accounted for by the concentration of certain items of capital expenditure in particular years—for example, the comparatively high rate of growth for the Agricultural Research Council in the current year is explained by the construction of two laboratories for food and meat research.

One of the most striking uncertainties in this analysis is that there is at present no way of knowing just what will be the contribution of the University Grants Committee to research expenditure in the universities. In 1966–67 this source contributed close on £50 million towards the cost of research, compared with the

£23 million or so which the research councils spent in or around the universities in the same year. It follows that much will depend on the settlement soon to be reached for the financing of the universities in the five years from September 1968. There is also some doubt about the way in which the sums available will be affected by the inevitable increase of the cost of carrying out scientific research in the years ahead. The report says that the council's working party on what is called "sophistication" should be ready soon, but there seems no prospect of being able to obtain a simple rule of thumb which can be applied across the board to anticipate the increasing cost of research.

The council takes a cautious line on space research. Its particular concern is to ensure that the relationship between British universities and ESRO should yield as much good science as possible, and the council gives a warning that it will be alarmed if resources provided for scientific research in space should be diverted to technological development. It does not deny the potential value of space applications but says that these must be considered and financed separately from the present budget. The council also resists the suggestion that space research should be transferred from the responsibility of the research councils and the UGC—a comment on the recent report of the House of Commons Select Committee on the Estimates, which recommended that the Ministry of Technology should assume direct responsibility for all forms of space research and development. Not merely, says the council, would such a step expose funds provided for science for use on a very large scale for nonscientific purposes, but it would violate the principle that the research councils should decide scientific priorities on the recommendations of scientists.

The council's argument about the proposal to build a 300 GeV proton accelerator within CERN is cautious. It acknowledges the success of CERN, at present based on the 28 GeV machine at Geneva and the accompanying storage rings. But participation in the construction of the 300 GeV machine would entail that the British investment in nuclear physics, in Britain and abroad, would work out at £34 million a year in 1977, which implies an annual increase of 7 per cent. The council has based its decision on the deliberations of a working

group under Professor Michael Swann with Dr J. B. Adams, Dr F. S. Dainton, Professor B. H. Flowers, Dr J. C. Kendrew, Sir Harry Melville and Professor A. B. Pippard as members. The report of the working group is not to be published, for the time being at least, but its argument is that the justification of the project rests entirely on its intrinsic scientific interest. One surprising aspect of the argument is that the council has been convinced that there would be no economic benefit in having the proton accelerator built in Britain, although of course there would be significant scientific benefits. The council's feeling is that the building of the new machine should not interfere with plans for development in medical, agricultural and environmental research. It adds its caveat about the need to avoid escalation before suggesting that the Government should participate.

Among the other activities of the council, the report singles out the work of the computer board, saying that a continuous review of the employment of computers in universities is being undertaken. There is to be a review of biological research in British universities based on a survey carried out in February this year and this, it is hoped, will reveal the present balance of activity in different fields of biology. The council is pleased with the way in which European science fellowships are being developed in collaboration with the Royal Society. A total of £50,000 has already been allocated to the Royal Society for planning a programme of scientific exchanges at post-doctoral level and the council says that £200,000 has provisionally been reserved for each of the two succeeding years. The council is also carrying out a study of the value of the British Antarctic Survey, although it is not clear from its report whether it has it in mind that the scale of the survey's operation should "continue at its present level, be run down or be increased". On the Naples Zoological Station (see Nature, 213, 221; 1967), the council has recommended that the British Government should contribute £28,570 a year so as to secure a seat on the council. On EMBO, the council is in favour of supporting the current programme of exchanges when the grant from the Volkswagen Foundation comes to an end in 1968, but it considers that the case for a European laboratory is not yet proved.

NEWS AND VIEWS

Nobel Prizes for Vision

THE award of the Nobel Prize for Medicine to Professors George Wald of Harvard, H. K. Hartline of the Rockefeller University and R. Granit of Stockholm is a welcome and imaginative step. The three people concerned are distinguished for their separate contributions to three separate parts of contemporary understanding of the processes of vision. One way and another, all of them have done a great deal to stimulate work in other laboratories. The result is that the physiology of vision has been transformed, in a comparatively short time, from what seemed to be a narrow and introspective specialism into a rapidly growing field of interest. And the objective, of course, is not merely an understanding of the mechanism of vision but a deeper insight into the nature of sensory processes of all kinds.

Professor Wald is a chemist by origin, and his contribution has been the identification and the study of the visual pigments and their chemical precursors. He, for example, was for a long time the driving force in the solution of the problem of rhodopsin. It is interesting and important that much of his influence on the development of this subject stems from his flair for expressing the results of his research with enormous clarity, and from his eagerness to spend time on doing this. Whatever the means, however, the result has been a dramatic advance in understanding in molecular terms of how light is absorbed by the visual receptors. One important by-product has been a deeper insight into the processes of colour vision. But the study of the visual receptors also promises to link up in important ways with work elsewhere in molecular biology on enzyme systems which involve the conduction of electrons along sheets of molecules the enzyme systems in mitochondria, for example. Nobody should be surprised that Professor Wald's work has posed as many questions as it has answeredthey are all of them important questions.

Professor Hartline works in a different line. He has made a lifelong study of the visual receptors in the

Behavioural Mutants

from our Cell Biology Correspondent

When it seemed likely that studies of the genetic basis of behaviour and memory were likely to yield some quick results, many molecular biologists toyed with the idea of changing to the new field, but as the complexity of the problems emerged all but a few lost their enthusiasm. Benzer, famous for his work on T phage, was one of those who determined to make the change. He chose to work with Drosophila; a shrewd choice for anyone trying to define the structures and events which underlie behaviour, for Drosophila, as well as

eye of the horseshoe crab Limulus, chosen for what seems to be the simplicity of its eye. He was, for example, the first to demonstrate that it is possible to make electrical recordings from single nerve cells. The study of Limulus eyes has provided all kinds of object lessons for the understanding of more complicated systems. Hartline and his collaborators have been concerned above all to use knowledge gleaned about the eye of Limulus as a means of constructing a mathematical representation for the functioning of an intact retina. Evidently this has important links with the way in which physiologists of all kinds are now preoccupied with understanding the ways in which living systems process information.

Professor Granit was awarded the prize in recognition of his work on the vertebrate eye, in the course of which he demonstrated inhibition in the retina, and revealed the principles of colour vision. Born in Finland, he graduated from the Swedish Normalyceum in Helsinki. After holding a fellowship of the University of Pennsylvania and a chair at the University of Helsinki, he became professor in the Caroline Institute in Stockholm in 1940. He was appointed to his present position of director of the Nobel Institute for Neurophysiology in 1945. He was president of the Royal Swedish Academy of Science from 1963–5, and is a foreign member of both the Royal Society of London and the American Philosophical Society.

In 1954, seven years after the publication of his first major work, Sensory Mechanisms of the Retina, Professor Granit was invited, on the fiftieth anniversary of Sherrington's own lectures in the same series, to deliver the Silliman Lectures at Yale. These were published as Receptors and Sensory Perception. In more recent years, Professor Granit turned his attention to motor physiology; an account of some of his work in this field, which brought him the Jahre and St Vincent Prizes, can be had from his contribution to the report of the first Nobel Symposium on Muscle Afferents and Motor Control, which he also edited.

offering the advantages recognized by the classical geneticists, has a well mapped genome and well documented behavioural patterns which potentially can be analysed with mutants. Starting with an inbred strain, it should be possible to study the direct relationships between individual genes and the nervous system if mutants with single step changes in a behavioural pattern can be isolated. The difficulty, of course, is devising a selection procedure which isolates such mutants in a single generation rather than progress-

sively over several generations. Progressive selection yields recombinant strains with multiple gene changes so it is virtually impossible to determine the effect of any one particular mutation on the nervous system.

In Proc. US Nat. Acad. Sci. (58, 1112; 1967), Benzer now reports the isolation in one generation of two mutants with changed phototactic behaviour. He devised a most ingenious selection technique, analogous to the counter current procedure used to separate mixtures of molecules, to isolate the two mutants. In essence, this involves putting Drosophila at the bottom of a tube over which is inverted a second tube. After arousing the flies a light is shone at either end of the joined tubes and the flies move in response to it. After 1 min the tubes are separated and new tubes attached to each and the process repeated for fifteen cycles. In model experiments, mixtures of wild type and wing deficient mutant flies, which also have poor phototactic response, were separated in this way.

Benzer then mutagenized with ethyl methane sulphonate (EMS) a population of male flies-strain Canton, Ohio-Standard—which he found forms a homogeneous population with strong phototactic response and then mated them with virgin X chromosome attached females. He used this unusual female strain as a genetic trick to ensure that all the male progeny received their X chromosome from the mutagenized male parent, not, as is usual, from the female. The twenty-six male progeny of this mating which lacked phototactic response were isolated by the counter current procedure. After a second mating of these males individually with virgin X attached females to distinguish between true behavioural mutants and flies which, although phenotypically non-phototactic, are genetically normal, he was left with two sex-linked mutants which had lost phototactic behaviour in one generation. Furthermore, the site of these two mutations must differ, for one mutant has abnormal wing veins whereas the other appears normal.

Phototaxis is obviously a complex behavioural pattern involving reception of stimuli, transmission and integration of nervous signals and the generation of a motor signal telling the fly to move towards light. A mutation altering any of these elements would alter phototaxis, but by isolating many different mutants it should be possible to analyse the wiring diagram of the nerve circuits and the biochemistry of the impulse transmissions involved in phototaxis. Moreover, the counter current selection method can obviously be adapted for such stimuli as gravity, odour and sound and, by using a two stage procedure, any two factors can be selected for independently. Although this remarkable work is only a beginning, it provides a method for the isolation of many behavioural mutants and ultimately the genetic analysis of behaviour.

Family of Proteins

from our Molecular Biology Correspondent

CERTAIN families of proteins—particularly the haemoglobins, the cytochrome cs and the lysozymes—have been the target of biochemical attacks in depth on broad fronts. Large numbers of these proteins have been sequenced, and it has been possible to draw broad conclusions about the number of positions in the chain which must remain invariant and the nature of the substitutions permissible elsewhere, and here and there some information has accrued on the effects of particular substitutions on aspects of the activity and structure

Sequence data on a considerable number of lysozymes are available, thanks mainly to Jollès and his collaborators, and his latest review (Bull. Soc. Chim. Biol., 49, 1001; 1967) draws together the large number of facts which have been uncovered. The vertebrate lysozymes are basic proteins, which are substantially similar in amino-acid composition, but show considerable differences in their sequences. It is possible to make some assertions at least about residues not specifically involved in the activity or in maintaining the conformation. Thus, one lysozyme (duck egg) has been described which is devoid of histidine. This appears to put paid to schemes involving histidine in the enzymic mechanism. The residues near the N-terminal end of the chain are also not involved, since two or three of these can be removed with an aminopeptidase without detriment to the function. The X-ray structure of hen's egg lysozyme indicates that three of the six tryptophan residues are clustered around the active centre; Jollès reports that two tryptophans, including one of the above three, try-108, can be chemically destroyed without observable diminution of activity. Even the number of disulphide bonds is variable. In hen's egg lysozyme, which by virtue of the X-ray structure is implicitly taken as the norm, there are four, in human lysozymes (milk and tears) three and in goose egg lysozyme two. This is also the order of thermal stability of the enzymes, the last, which also has a low tryptophan content, being very unstable. The structural lability is correlated with high enzymic activity, which one would like to believe reflects a readily responsive conformation (in terms, for example, of the induced-fit concept). A bacteriophage lysozyme, sequenced last year by Inouye and Tsugita, has the same substrate specificity as the mammalian lysozymes. but has very different sequence and composition, and may well be unrelated.

The most unexpected observation comes now from Brew, Vanaman and Hill (J. Biol. Chem., 242, 3747; 1967), who have determined the sequence of the milk protein α-lactalbumin. This is a component of the lactose synthetase system, and catalyses the formation of the same glucopyranosyl linkage which is broken by the lysozymes. It is astonishing to find an extensive and unmistakable sequence homology with hen's egg lysozyme. Forty of the 123 residues of α-lactalbumin are identical with those in the corresponding positions in lysozyme. A further 27 residues are of similar type ("conservative" substitutions). In both proteins there are four disulphide links; two of these only have so far been determined in lactalbumin, and these are identical to their counterparts in lysozyme. To achieve the best homology, two double-residue and four single-residue gaps must be allowed in the lactalbumin sequence, and two double-residue gaps in lysozyme. A remarkable point of difference is that, despite the homologies, α-lactalbumin is an acidic protein, whereas lysozyme is basic (the isoelectric points are pH 5 and 10.5). It seems then that the two proteins derive from a common precursor, and that a duplication of genes occurred at some stage, which was followed by the separate evolution of α-lactalbumin in the mammals.

Hybrid Cells and Gene Location

from a Correspondent

When animal cells from two different species are mixed and grown in culture, a few hybrid cells are formed. By using parent cells with appropriate genetic markers, the hybrids can be selected for further study. These newly formed hybrids have a chromosome complement derived from both parents. The hybrids are not just bizarre novelties—one of their uses, as Weiss and Green show (*Proc. US Nat. Acad. Sci.*, **58**, 1104; 1967), can be to locate genes to particular chromosomes. These authors used as parents cells of mice deficient in thymidine kinase and resistant to 5-bromodeoxyuridine (BUdR) and human cells self-sufficient for the kinase. The hybrids were selected and they too are now self-sufficient for thymidine kinase because of the presence of human kinase genes. After about 20 generations, the hybrids still have all their mouse chromosomes, but have only 2-15 of the original 48 human chromosomes. If gene markers are also lost, can these be assigned to the lost chromosomes? Addition of BUdR kills these hybrid cells which are self-sufficient for thymidine kinase, while cells lacking the kinase survive. Chromosomal analysis of the hybrids has shown that human chromosomes of the group 6-12-X were rare in the BUdR-selected hybrids, but more frequent in cells susceptible to BUdR. Gene mutation at the kinase locus was ruled out and so the human gene(s) controlling thymidine kinase was concluded to lie on a 6-12-X group chromosome.

Analysis of cell surface antigens, cell morphology and chromosome complement of the hybrids has indicated that genes for surface antigens are widely distributed throughout the human genome, but genes for cell morphology are less widely so. Scaletta et al. (Genetics, 57, 107; 1967), using hamster-mouse hybrids, show that a similar approach to gene mapping is feasible in other species. But in this hybrid the chromosomal changes, especially in the mouse genome, make it difficult to locate genes to chromosomes. This hybrid contains an enzyme (glucuronidase) of hybrid structure, so enzyme sub-units can be used as another genetic marker. Other hybrid enzymes have been found by Weiss and Ephrussi in rat × mouse hybrid cells.

An important feature of the mouse-human hybrid is the preferential loss of human chromosomes. The human cells were of a cell strain where cell death occurs naturally after about 50 generations, while the mouse cells were of an established cell line and are potentially capable of surviving independently. Although the hybrid seems to have cell line properties, the human complement has not had immortality conferred on it by its association with the mouse environment.

To extend work on mammalian genetics, many more marker genes are needed; also mutant cells must then be confidently isolated. Puck and Kao (Proc. US Nat. Acad. Sci., 58, 1227; 1967) show how the latter requirement can be very simply achieved with nutritional mutants. They use a technique by which the wild type cells are selectively killed off, leaving the mutants. But chromosomes must also be more specifically identified than is possible at present, especially in man and mouse. Moreover, if gene location is to be possible it will be necessary to recognize structural genes from their operators and regulators, and indeed to show that these latter exist in mammalian cells.

Viral Nomenclature

The latest edition of *Progress in Medical Virology* (9, 476) describes how the International Committee on the Nomenclature of Viruses was set up. Until recently the nomenclature of viruses has been governed by a subcommittee of the International Committee on Bacteriological Nomenclature. This unsatisfactory state of affairs was brought to an end by the voluntary dissolution of the subcommittee and its replacement by a Provisional Committee on Nomenclature of Viruses which has now become the permanent ICNV responsible to the International Association of Microbiological Societies.

The committee was established by inviting each national microbiological society to nominate up to five delegates, who met for the first time in Moscow in July 1966. Under its president, Professor P. Wildy, the ICNV agreed to examine all true viruses, to define evident groups at the generic level and to suggest names for them. Four working subcommittees were established to deal with viruses of vertebrates, invertebrates, bacteria and plants; a fifth is concerned with the general utility and practicability of cryptograms in virology.

There is considerable disagreement within the ICNV; some favour an attempt at phytogenetic classification—despite the inevitable mistakes—and a binomial nomenclature, while others believe that the extent of knowledge about viruses is too small for this to do anything more than fossilize the mistakes. The subcommittees are also beset with difficulties of language—English must be used because Anglo-Saxons and Americans cannot express themselves in anything else, but this poses problems for abbreviation of names and their transliteration into Cyrillic and other scripts.

Despite difficulties and disagreements the subcommittees are working towards a tentative binomial nomenclature. They are studying criteria and suggesting definitions for species genera and subgenera. They are to select a type species for each genus and subgenus and to consider generic names. The cryptogram is also likely to be tried experimentally and the members of the subcommittee considering this are representatives of different branches of virology.

The ICNV has produced twelve rules so far. The code of bacterial nomenclature shall not be applied to viruses and the new code shall be international and universally applied to all viruses. An effort will be made to produce a latinized nomenclature, and where possible existing latinized names shall be retained. There will be no law of priority, no sigla shall be introduced, nor shall person's names or nonsense names. For pragmatic purposes the species is considered to be collections of viruses with like characters, and the genus is a group of species sharing certain common characters. Some orthographic rules have been approved. The ICNV is continuing its work towards a viral nomenclature.

Satellite Geodesy in Europe

from a Correspondent

For more than a year, laboratories in fourteen countries in western Europe have been collaborating in a programme of simultaneous observation of the Echo 1

and 2 satellites. About twenty observing stations scattered throughout the member countries are regularly making photographic observations of the two satellites so that knowledge of the size and shape of Europe may be improved. The camera stations photograph one of the satellites against the star background and, when this is achieved simultaneously at two or more stations, the rays to the satellite from the cameras form the sides of a triangle or a polyhedron from which it is possible to deduce something about the relative positions of the stations. For example, at about 22.25 U.T. on April 16 this year, the cameras situated at Graz in Austria, Meudon and Strasbourg in France, Frankfurt and Munich in western Germany, San Fernando in Spain and Malvern in England all photographed the Echo 1 satellite. Observations such as this establish strong geodetic ties between the respective camera stations. The observations need to be extremely accurate, about a millisecond in time and a few seconds of arc in position, if any improvement is to be made on the existing knowledge of the shape of Europe.

Photographic observations of satellites can only provide an angular measurement, and, in order to determine the distances between the stations, a scale must be introduced into the system. This can be done by assuming that the distance between two stations of the network is known or by measuring the distance of the satellite directly. One method of ranging a satellite is by the use of a pulsed laser and work in this field is being actively pursued in the United States and France. At a conference on Satellite Geodesy in Paris in May and at the recent COSPAR meeting in London, American and French workers estimated that accuracies of a few metres in the measurement of range are now possible by the use of lasers, although this is, of course, restricted to satellites which carry specially constructed corner reflectors. Eventually, an accuracy of about 10 metres will be possible for the position of each of the camera sites. Because each site can be carefully placed within a national geodetic datum, the relative positions of any two places in Europe should be determined with comparable precision.

This programme of observations of the Echo satellites, organized by the Western European Sub-Commission of the International Commission for Artificial Satellites of the International Association of Geodesy, is not the only one which has been carried out recently in Europe. The United States Coast and Geodetic Survey has used portable BC4 cameras to establish sites at several points in Europe, including Edinburgh in Scotland and Munich in western Germany. These sites are occupied for a few weeks while observations are being made and the cameras then move to another This European programme is part of a location. larger world wide triangulation programme of the United States Coast and Geodetic Survey. In addition, the Smithsonian Astrophysical Observatory has camera stations at San Fernando and Athens which are actively participating in a geodetic programme. The National Aeronautics and Space Administration is also undertaking geodetic studies which include observations from Europe. The Geos A flashing light satellite has also been observed on several occasions from European camera stations, particularly Zimmerwald in Switzerland and Malvern in England. In general, satellite geodesy in Europe seems to be growing well on the observational side; the great need now is for work on the analysis of observations so as to make more widely available the results of what has been done.

Meteor Showers Ahead

from a Correspondent

THE two important meteor showers of November and December—the Leonids and the Geminids—are markedly dissimilar in character. The Geminid shower provides one of the most reliable meteor displays, with only statistical variations in the rate from year to year, but the Leonids are typical of another type of stream in which remarkable showers occur periodically, indicating an intense localized swarm of particles in the orbit.

Some Geminid meteors can usually be seen between December 7 and 15, but the maximum occurs on December 13 or 14, when an observer may see as many as fifty meteors an hour with the naked eye if the sky conditions are good. Thus the Geminids are one of the richest showers of the year. Oddly enough, however, there are no records of a shower on these dates in antiquity, and the shower does not seem to have appeared with sufficient strength to be recognized until 1862.

Its origin is an enigma. The formation of meteor streams is now generally supposed to be a result of the disintegration of comets as they swing around the Sun. In favour of this view, several meteor streams are known to move in the same orbits as certain comets —in fact, one of the first cometary associations to be demonstrated was that of the Leonids and Tempel's comet. The Geminids have never been satisfactorily accounted for by this hypothesis. Their orbit is peculiarly small, smaller than that of any known meteor stream or comet and of most asteroids. Geminid meteors are also unique in having densities two to three times greater than the average density of meteoroids. The explanation of these abnormalities by an old parent comet in which the meteoric dust is likely to be more compact, coupled with perturbations of the orbit by close approaches to the planets, cannot be ruled out, but the exact mechanism remains a mystery.

Interest in the Leonids, which flagged somewhat as a result of the disappointing maxima of 1899 and 1932, has revived after the historic display over North America in 1966. Last year the Soviet astronomer I. S. Astapovich predicted that the maximum of the 1966 Leonid shower would occur on November 17 at 10.00 U.T.—a forecast which was very nearly correct. Observing stations in northern Siberia, the only region of the Soviet Union where the radiant was above the horizon during darkness, recorded maximum activity between 11.50 and 12.30 U.T. on November 17, and a zenithal hourly rate at peak activity of 130,000, in close agreement with observations in the United States. This year, Russian astronomers are expecting the maximum to occur on November 17 at 17.00 U.T. No predictions are being made of the strength of the shower, and perhaps astronomers are remembering that the failure of the shower to return as predicted in 1899 was, in the words of the American meteor physicist C. P. Olivier, "the worst blow ever suffered by astronomy in the eyes of the public".

Bacterial Inhibitors in Milk and other Biological Fluids

by B. REITER J. D. ORAM

In common with other body fluids, milk contains several bactericidal and bacteriostatic factors.

National Institute for Research in Dairying, Shinfield, Reading

THE bactericidal and bacteriostatic properties of milk were first described at about the same time as those of blood, but naturally have not attracted the same attention. Most of the relevant literature consists of observations that various pathogenic and saprophytic bacteria are killed or their growth temporarily inhibited by cow's milk¹-8. It has become increasingly evident that milk contains several inhibitors ("lactenins") which differ in their antibacterial specificities and, moreover, are not confined to milk.

In this article some of the inhibitory systems in milk are considered in relation to those present in other biological fluids.

Lactoperoxidase/Thiocyanate/Peroxide

In 1924 Hanssen¹ suggested that the bactericidal properties of milk against Salmonella typhosa and S. paratyphosa are the result of its peroxidative activity. A close correlation between the inhibition of group N streptococci and the progressive heat inactivation of lactoperoxidase (LP) (ref. 5) indicated that the lactenins active against various streptococci (group A, F, G, H, K, L and N) are associated with lactoperoxidase 6-9. It is now well established that streptococci and other bacterial species are inhibited only in the presence of thiocyanate, indican or iodine 9-14, which are found in milk and other biological fluids. The concentration of NaSCN required for inhibition is only 0.2 μg/ml. in the presence of lactoperoxidase, but about 100-200 μg/ml. in its absence 9,10. Lactoperoxidase in the presence of SCN- and H₂O₂ completely inhibits hexokinase and partially inhibits other glycolytic enzymes of resting streptococci. Moreover, strains of streptococci which resist this inhibition possess an enzyme which catalyses the reduction of the intermediate oxidation products of SCN- by NADH, or NADPH. The inhibitor in milk is very unstable and has not been isolated, but it resembles sulphur dicyanide, a minor product in the non-enzymatic oxidation of SCN-by H₂O₂ (ref. 15); both inhibit hexokinase but not phosphohexokinase and both are reduced in the presence of NADH₂ or NADPH₂, by extracts of LP-resistant but not LP-sensitive strains. These results led us to suggest that the inhibitory product formed in milk during the oxidation of thiocyanate is either S(CN)2 or a substance similar to it11.

Xanthine Oxidase

Green and Pauli¹⁶ demonstrated that a variety of pathogenic Gram-positive and Gram-negative bacteria were inhibited by $\mathrm{H}_2\mathrm{O}_2$ produced by xanthine oxidase in media containing xanthine. But because milk contains only low concentrations of the substrates for xanthine oxidase it is unlikely that bactericidal concentrations of $\mathrm{H}_2\mathrm{O}_2$ are formed. The small amounts of peroxide produced either by xanthine oxidase or by the non-enzymatic oxidation of the ascorbic acid in milk, however, could cause the inhibition of organisms which do not normally produce $\mathrm{H}_2\mathrm{O}_2$ or are not susceptible to inhibition by peroxide itself if the peroxide is utilized in the lactoperoxidase-catalysed oxidation of thiocyanate.

Lactotransferrin

Milk contains an inhibitor against B. subtilis and B. stearothermophilus which is very heat stable (90° C for

60 min) but is inactivated by trypsin, FeSO₄ and less effectively by MgSO₄ (refs. 17 and 18). This inhibitor has been identified as the red iron-binding protein, lactotransferrin¹⁹. During the main period of lactation cow's milk contains only low concentrations of lactotransferrin, but the concentration gradually increases during the drying-off period (Table 1). An inhibitor fraction purified from the dry period secretion by filtration through 'Sephadex G-200', followed by zone electrophoresis on a block of 'Pevikon G870', was found to have two components in the ultracentrifuge with S_{20} values of about 12Sand 20S. Immunoelectrophoresis revealed that these fractions contained lactotransferrin and casein. Purified lactotransferrin inhibits the growth of B. stearothermophilus and B. subtilis and its inhibitory activity is suppressed by ferrous ions. When not fully saturated with iron, lactotransferrin (but not serum transferrin) has no effect on the activation of spores of B. stearothermophilus but inhibits their germination.

Table 1. INHIBITION OF Bacillus stearothermophilus by the secretion of NON-LACTATING UDDERS

• • •	3	1:160
,	3	1:320

*Inhibition expressed in units/the reciprocal of the highest dilution of 0.25 ml. of material which gives a visible zone of inhibition when placed in a well in agar containing a standard inoculum of heat shocked spores of Bacillus stearothermophilus.

Complements and Antibodies

Because sheep erythrocytes are not haemolysed by raw milk it is generally assumed that bovine milk does not contain complement. As early as 1907, however, it was demonstrated 20 that while sheep erythrocytes are not suitable for the detection of bovine complements guineapig erythrocytes are readily haemolysed by raw milk. Using a conglutinin test (suggested by Dr P. J. Lachmann, Department of Pathology, University of Cambridge) we frequently detected complement in bulk milk, but not in all samples of milk from individual cows. It was regularly present towards the end of the lactation period, in the secretion of the non-lactating udder, in the colostrum and in the milk for some weeks afterwards (Table 2).

Milk does not normally contain high titres of antibodies, but it often contains low titres of agglutinins-natural antibodies—against lactic acid bacteria^{5,8,21}. Boyden²² suggested that natural antibodies need not necessarily arise in response to a specific infection but may be induced by contact with "antigenic determinant groups, particularly those occurring on polysaccharides shared among many organisms as well as animal and plant tissues" In ruminants, where non-specific antigens could be derived from plant tissue and rumen micro-organisms, conditions may be particularly favourable for the formation of such natural antibodies. It is now evident that in many instances the bactericidal activity of raw milk against Gram-negative organisms3 may be attributed to the killing effect of complement and antibodies. Raw milk also reduces the count of Gram-positive organisms through agglutination or increase of the length of the streptococcal chains by an end-to-end agglutination3,5,23

Table 2. COMPLEMENT TITRES IN BLOOD SERUM, MILK AND SECRETION OF NON-LAGFATING QUARTERS

	Number of cows	Titres
Blood serum	6 6	$1:16 \\ 1:32$
	Number of quarters	Titres
Milk before drying off	16 6 2	<1:2 1:2 1:4
	Number of quarters	Titres
Secretion after drying off (14 days	2 9	<1:2 1:2 1:4
	10	1:8

Although the occurrence of immune globulins in colostrum and in the secretion of the non-lactating udder is well authenticated, little attention has been paid to their specificity against udder pathogens. We examined the levels of agglutinins and complements in blood sera, milk and dry udder secretion of fifty cows over a period of 2 yr. Although Staphylococcus aureus and Streptococcus uberis were the only endemic organisms in this herd, agglutinins were also detected against Streptococcus pyogenes, Streptococcus dysgalactiae, Streptococcus agalactiae, Escherichia coli and Corynebacterium ulcerans at titres up to 1:640 in the blood, milk and secretion of different animals.

Leucocytes and Mastitis

The number of leucocytes in milk is important in the defence against mastitis pathogens, but the experimental evidence on the relative importance of cellular and humoral factors in the prevention of udder infections is conflicting. We have challenged individual udder quarters containing various levels of leucocytes, agglutinins and complement with S. aureus. When ten colony forming staphylococci (S. aureus, strain m, phage type 6/7/54/75/77/52B) were placed beyond the teat canal into the teat cistern of normal udder quarters containing 104-105 leucocytes/ml. (a few per cent at the most being polymorphonuclear leucocytes (PMN)), the udder invariably became infected. When, however, leucocytosis was induced by infusing 50 ml. of 0.14 molar NaCl into each quarter before the introduction of the staphylococci the greatly increased number of leucocytes, particularly PMN, prevented infection (Table 3). Table 3 is representative of experiments performed with ten cows.

Dry period quarters containing 10⁵–10⁶ leucocytes/ml. (up to 25 per cent PMN) seemed to be more resistant to infection than lactating quarters. When six dry quarters were each infused with twenty staphylococci, only one quarter became infected; infusion with two thousand staphylococci resulted in the infection of thirteen out of eighteen dry quarters. Prior infusion of eleven quarters with saline increased the number of leucocytes to a maximum of 10⁸/ml. (up to 80 per cent PMN) and on subsequent inoculation with staphylococci only one quarter became infected. In two quarters which became infected after saline infusion the number of PMN failed to increase above 10⁶/ml.

For 2 years we attempted to correlate the presence of complements and/or antibodies with the resistance of the udder against infection with staphylococci or streptococci and came to the conclusion that high numbers of PMN prevented infection irrespective of the presence of complements or antibodies.

Comparison of Bacterial Inhibitors in Milk with those in some other Biological Fluids

There is now increasing evidence that two of the inhibitory systems in milk are also minor defence mechanisms in animals and man.

Thioeyanate is widely distributed in body fluids and, because the mammary gland, like the salivary gland, is of ectodermal origin, we suggested^{7,8,11} that the inhibitory system found in milk also operates in saliva; this has recently been confirmed^{12,13}. Besides streptococci and lactobacilli, *E. coli* and *S. aureus* are also inhibited in vitro by milk¹³ if an exogenous, non-microbial H₂O₂-generating system such as xanthine oxidase and xanthine is available. Because peroxidase and lysozyme are both present in the mammary, salivary, Harderian and lacrimal glands—all of ectodermal origin—they may, under aerobic conditions, control the bacterial floras of the nasal, oral and ocular areas²⁴.

Thiocyanate is also oxidized by myeloperoxidase²³ and because the rate of H₂O₂ formation by PMN is greatly enhanced during phagocytosis we suggested that this could lead to the formation of antibacterial substances¹¹; this seems to have been recently confirmed²³, although the authors interpret their results differently. Thus the LP/SCN-/H₂O₂ inhibitory system may act not only in milk and saliva but also in phagocytes, and may explain why complements and agglutinins have not been demonstrated to effect the elimination of staphylococci by PMN in the udder.

In addition to its antibacterial activity, the LP/SCN-/ H_2O_2 system also affects bovine spermatozoa. Unheated milk was once used as a diluent for bull semen and its pronounced spermicidal effect has been ascribed to "lactenin". Because the spermicidal and bactericidal properties of milk are similarly affected by heat and reducing agents, we examined the effects of LP and SCN-on bovine spermatozoa and found that their penetration into cervical mucus was impaired by the addition of peroxidase and thiocyanate²⁸. These observations may help to explain the widespread but unconfirmed belief that feeding cattle with kale (an excellent source of glucobrassicin, a precursor of thiocyanate²⁹) affects the conception rate in cows³⁰.

An antibacterial action of lactotransferrin similar to that in milk has also been demonstrated in saliva, bronchial and nasal secretions, tears, hepatic bile, pancreatic cyst fluid, seminal fluid, cervical mucus and urine in man. With fluorescent-labelled antibodies, lactotransferrin was detected in the glandular acini but not in the epithelial lining of the bronchial wall and submaxillary glands; it has also been demonstrated in the lumen of the galactophorus ducts of a human non-lactating mammary gland^{31,32} and may protect the mucosa against bacterial invasion.

Since the original report³³ that the iron-binding protein of human blood sera inhibits Salmonella dysenteriae the bacteriostatic activity of transferrin has been repeatedly confirmed. The lack of activity of bovine serum transferrin against B. stearothermophilus is surprising and as yet unexplained. More work is needed to determine the reason for the differences between the effects of transferrin and lactotransferrin on bacteria. It is of considerable interest, however, that Rogers³⁴ recently found that

Table 3. Effect of induced leucocytosis in the infection of single lactating quarters with low numbers of Staphylococci

Cow 297	Leuco- cytes/ml.	RF* % PMN	Staph./ml.	Leuco- cytes/ml.	RH % PMN	Staph./ml.	Leuco- cytes/ml.	LF* % PMN	Staph./ml.	Leuco- cytes/ml.	LH % PMN	Staph./ml.

^{*}Infused with 50 ml, of physiological saline.

Inoculum Staphylococcus aureus m phage type 6/7/54/75/77/52B, 10 colony forming units/quarter.

RF, right fore; RH, right hind; LF, left fore; LH, left hind.

Clostridium welchii type A is inhibited by unsaturated serum transferrin in the presence of $\beta 2$ or $\gamma\text{-globulin}$ or a mixture of both; these findings should help to clarify the nature of the various blood sera inhibitors.

We thank Dr G. C. Cheeseman for the determination of the sedimentation constant of the lactotransferrin.

Note added in proof. It has been found that the infusion of saline into udders produces leucocytosis because of the presence of pyrogens. Infusion of pyrogen-free water fails to induce leucocytosis and less than 1 µg of purified lipopolysaccharide (E. coli 055: B5, Difco) fails to produce leucocytosis in 4-5 h.

Linked Groups of Residues in Immunoglobulin K Chains

C. MILSTEIN MRC Laboratory of Molecular Biology, Cambridge

Crossing over theories have been advanced to explain antibody variability, and the simplest involves recombination between the elements of an "antibody gene pair" containing two versions of the variable section of the molecule. Data now seem to require at least three versions of the same section.

It is now generally accepted that the remarkable degree of variation in the primary sequence of the immunoglobulin chains is related to combining specificity, especially because the successful refolding of antibody molecules in the absence of antigen has provided strong evidence that such specificity is dependent on covalent structure. The present understanding of the heterogeneity of the peptide chains has been derived mainly from studies of the monoclonal immunoglobulins produced in association with myelomatosis of men and mice. Thus it seems that immunoglobulin light chains are made up of a C-terminal section, with a sequence that is characteristic of the chain type and which is common to many different clones, and an N-terminal section specific to the clone of origin. Specific antibody activity is seldom associated with specific chain types, and so antibody specificity should derive primarily from the alternative amino-acid sequences of the N-terminal sections. The variability of the Nterminal half of light chains seems thus to be of fundamental importance to the understanding of the mechanism of antibody specificity.

Of the 107 residues (reviewed in ref. 1) of the N-terminal section of human x chains, forty-two have been found to be identical in the individual proteins studied. Other residues, however, change only in isolated cases, such as residue No. 2 which was substituted in one out of seventeen proteins studied. In these cases the substitutions involve homologous residues (Ser/Thr; Val/Ile, and so on). Thus about half of the residues in the N-terminal section vary only in isolated cases or not at all.

Of the others there are many positions which contain one or two alternative residues. Occasionally a third residue is also present in these positions. In several instances these two alternatives involve homologous residues (Asp/Glu; Val/Leu; Thr/Ser), but in others these are certainly non-homologous (that is, Arg/Pro at position 18; Gln/Arg at position 24).

There are, on the other hand, positions that are extremely variable, and the best examples are found in two clusters. The first occurs around residue 30/32 where several extra residues have been observed in some proteins^{2,3} and the second is in residues 92, 93, 94 and 96 (ref. 4), where both homologous and non-homologous variants occur. Other clusters may still appear in sections of the molecule less extensively investigated.

The presence of positions that contain chiefly two alternatives is particularly interesting. Two alternatives are commonly found in certain positions of many proteins

Residues identical in all proteins have been omitted. Variants of basic sequence are given as breaks of solid line; Roman numbers indicate that the variant is the same residue of the corresponding basic sequence. All variants can be one step mutations from basic sequence.

resulting from allelic genes, and the first question to answer is if these two alternatives are allelic forms of the same structural gene. A typical case is the N-terminal residue. Both Asp and Glu are found in that position, Asp being present in about 60–64 per cent of the cases. Because λ chains with N-terminal Asp or Glu have not been reported, the N-termini of normal light chains should represent the N-termini of their \varkappa chains. A search of light chains of twelve normal individuals showed that all of them contained both Asp and Glu as N-termini, suggesting that these do not behave like allelic markers (Feinstein and Milstein, unpublished).

The second question to ask is whether there is linkage between the individual residues in the positions along the chain which have a choice of two (or mainly two) variants. I have selected stretches at both ends of the N-terminal half of x chains to do further studies of the nature of the variations. New peptides, related to residues 1-24, are shown in Table 1. When these results are added to other known sequences (Table 2) of the N-terminal quarter of the x chains variable stretch, strong linkage seems to be quite apparent, especially if one assumes three linkage groups. The first twenty-four residues in all the known proteins fall into one of the three basic sequences, with the exceptions shown in Table 2. Smithies has recently proposed that only two linkage groups appear to be involved, and so I would like to discuss the reasons for proposing at least three linkage groups. The combination Glu...Thr...Leu is present in the proteins that are

assumed to belong to the third linkage group, and none of these residues occurs in proteins defined as of groups I or II. Furthermore, the Leu of Rad in position 21 is also found in protein Fr 4 but in none of the proteins listed as from the basic sequence I or II. For one group of proteins to originate by crossing over of the other two,

several crossings over in identical places plus identical point mutations should have occurred, while the general patterns of the proteins of a group show very isolated examples of crossing over. If three basic sequences are assumed only two residues (No. 4 of protein Cu and 17 of Rad) could originate from crossing over (Table 2), while the other six variants appear as isolated point mutants. Another peptide, related to the stretch of residues 62–77, does also fit in the three basic sequences pattern (Table 3).

I have isolated in several proteins a peptide sometimes referred to as "switch peptide", which appears to belong to residues 104 to 107. This is of interest to provide information of the variability at the other end of the N-terminal half. Here also either of two residues occurs in positions 104 and 105, but in this part of the molecule no linkage is disclosed between these two (Table 4). It is as if, unlike the N-terminal section, frequent crossing over gave rise to these random combinations.

The occurrence of residues that do not fit in a crossing over pattern between two genes is too frequent to be overlooked. Such residues are often non-homologous and are scattered along the chain, although some are clustered after residue 90 (Table 4). The occurrence of some of the variants between residues 91 and 96 (Table 4) is difficult to interpret, unless one assumes that more than three sequences cross over or that they arose by some mutational event either in the germ line or as a result of mistakes during transcription or translation. It is interesting nevertheless that, for example, all four proteins listed as of sequence I contain Leu in position 94, unlike the examples of sequences II and III. I am not considering here the large differences after position 30 because the occurrence of a deletion (or addition) makes that part of the sequence more difficult to interpret with the very scanty amount of data known.

In λ chains there are not many well defined positions offering a choice between mainly two residues (reviewed in refs. 1 and 6); the best one is at position 10. Unlike the comparable stretch of x chains, no significant linkage group can be proposed. The four known Ala at position 2 present with Ser at position 13 are so far the strongest example of linkage. In other words, the situation here resembles the randomness described in the switch peptide of x chains (Table 4). Finally, I would like to emphasize that, if one assumes theories involving crossing over between two strands, the number of variants that remain unexplained in both types of chain is in fact larger than the number explained.

For reasons put forward previously1,3, it is unlikely that the C-terminal half of the x chain is coded for by more than a single gene. Three or more structural genes seem to code for the N-terminal half, and so it seems necessary to assume some mechanism of chromosomal rearrangement or insertion involving "half genes". Unless, however, a very large number of genes is proposed in the germ line3, an added mechanism of somatic hypermutation should operate on the variable section of the gene.

In this article I have used data obtained from manuscripts in press, for which I thank Dr Hilschmann and Dr Hood. I also thank my colleagues for helpful discussions, especially Drs Crick and Brenner.

Structure at the Hinge Region in Rabbit Immunoglobulin-G

D. S. SMYTH S. UTSUMI

National Institute for Medical Research. Mill Hill, London, NW7

The hinge peptide of rabbit IgG has an unusual amino-acid sequence. In containing three prolines in a row it is unique among known protein structures.

THE H chain of immunoglobulin-G (IgG) consists of two segments, the Fd and Fc fragments, coupled through a hinge region which is singularly exposed to enzyme attack. The Fd section has a variable amino-acid sequence and participates in antigen binding whereas the Fc section has a constant sequence and does not bind antigen.

Our experiments establish that there is a highly reactive disulphide bridge in the centre of the hinge region which seems to span the two H chains of the four chain IgG

molecule. We have identified the position of the reactive cystine and the amino-acid sequence of the surrounding area (Fig. 1). Galactosamine, a carbohydrate not previously reported in IgG, is present on 35 per cent of the H chains; it is located on a threonine residue immediately preceding the reactive disulphide bridge. The sites in IgG which are sensitive to attack by papain, and by pepsin, have been identified by examining the peptides liberated from the hinge region by the action of these

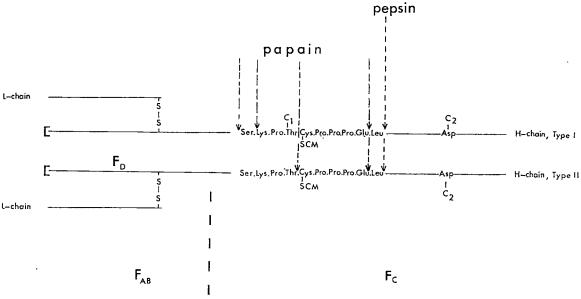

Fig. 1. Chain structure of rabbit IgG, showing detailed structure at the hinge region. The arrows indicate alternative sites of papain cleavage.

Molecules lacking the carbohydrate C₁ undergo additional cleavage at the NH₂ group of the adjacent cystine residue.

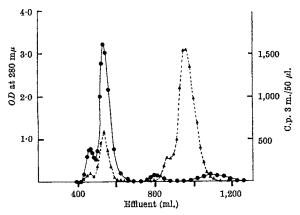

Fig. 2. Gel filtration of a papain digest of reduced carboxymethylated P(ab'), fragment of IgG. F(ab'), (250 mg) was reduced at pH 8·0, 30° C, for 6 h in 0·0014 molar mercaptoethanol, and then was incubated with 0·0022 molar ¹⁴C iodoacetic acid (0·7 $\mu c./\mu$ mole) at pH 8 for 1 h. After removal of the reagents by dialysis, digestion was carried out with crystalline papain at a ratio of enzyme: substrate of 1:100 in the presence of 0·0014 molar mercaptoethanol at pH 7·0, 3° C, for 24 h. The digest was applied to a column (170 × 3 cm) of 'Sephadex G-75' and eluted with 0·2 molar ammonium bicarbonate—ammonium acetate pH 8·7.

enzymes; the presence of the carbohydrate C₁ exerts a controlling effect on the sites of papain cleavage. The hinge peptide containing the reactive disulphide, Cys-Pro-Pro-Pro-Glu-Leu was located at the COOH terminus of the H chain in F(ab')₂. This peptide was extremely resistant to enzyme attack. The region flanking it, on the other hand, was cleaved by papain in a variable manner, perhaps reflecting heterogeneity of structure elsewhere in the molecule.

An immunoglobulin molecule radioactively labelled at the hinge region was obtained by reducing pooled rabbit IgG in mild conditions (0.0028 molar mercaptoethanol for 1 h at $p{\rm H}$ 8) and then blocking the released sulphydryl groups with $^{14}{\rm C}\text{-iodoacetate}$. These conditions were

designed to affect a single disulphide bridge1: approximately 80 per cent of the reduced alkylated IgG, dissociated into half molecules at pH 2.4 (refs. 2 and 3). expected cleavage of the labelled molecule by papain to leave the radioactivity either in the Fab fragment or in the Fc fragment, according to which side of the hinge region the enzyme attacked. When the molecule was digested with the papain, however, neither fragment was substantially labelled; most radioactivity appeared in a peptide fraction. Fab and Fc were recovered in the normal way, and so it was clear that one or more peptides containing labelled cysteine had been split out from the hinge region of IgG, following the action of papain. The peptide fraction, which contained 80 per cent of the initial protein bound radioactivity, was resolved by gel filtration on 'Sephadex G-25' into two principal components: fraction A with 16 per cent and fraction B with 60 per cent of the total radioactivity. Both fractions contained a mixture of peptides. When their structure had been elucidated, a composite sequence could be proposed for the hinge region.

From fraction B, ion exchange chromatography on 'Dowex 50-X2' provided one radioactive peptide and a variety of unlabelled peptides. The radioactive peptide was obtained in a pure state by further chromatography on 'Dowex 1-X2' and was isolated in two forms, one of which had a blocked NH₂-terminal residue:

The blocked end group was identified as a derivative of thiazane carboxylic acid, formed from the carboxymethylcysteine residue (CM-Cys) of peptide I during the isolation procedure. This terminal residue has not previously

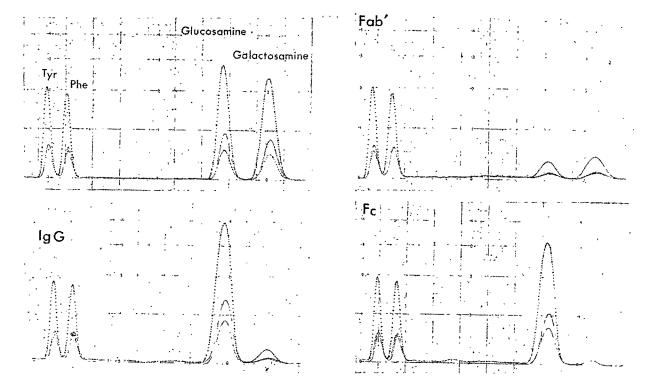

Fig. 3. Localization of glucosamine and galactosamine in rabbit IgG. Rabbit IgG, F(ab'), fragment, or Fc fragment was hydrolysed in 3 normal hydrochloric acid at 110° C for 12 h. After the hydrolysis, residual peptides and amino-acids were removed on a column (10×0.9 cm) of 'Dowex 2-X8' operated with 1 per cent N-ethylmorpholine acetate pH > 0 as eluent. (Details of the method will be published elsewhere.) Tyrosine and bhenylalanine (0.2 μ mole) were added as markers to the peptide-free hydrolysates. The hydrolysates were analysed at 50° C on a column ($bb \times 0.9$ cm) of IR-120 with 0.4 molar sodium citrate pH 5.28 as eluent. For comparison, the first chart shows an analysis of a synthetic mixture containing glucosamine and galactosamine (0.6 μ mole) together with tyrosine and phenylalanine (0.2 μ mole).

been encountered in analytical studies of proteins and peptides. In these experiments, ring closure of terminal CM-cysteine was found to take place in mild conditions, occurring even during chromatography at pH 3·2.

The cyclization reaction could be used to advantage in the purification of peptides that have CM-cysteine at the NH_2 -terminus, and it may account for the frequent difficulties in the analysis of CM-cysteine.

The hinge region represents the portion of the H chain that is present in the peptic fragment, $F(ab')_2$, but absent from the papain fragment Fab; it appears to be the only site of inter-H chain disulphide bridges. An attempt was made, therefore, to isolate the hinge peptide containing the labile disulphide from the 5S divalent fragment, $F(ab')_2$, and accordingly a similar procedure of mild reduction (0·0014 molar mercaptoethanol), alkylation, and digestion with papain was applied to the peptic fragment in place of whole IgG. With 1·4 groups of carboxymethylcysteine in 1 mole of $F(ab')_2$, 95 per cent of the reduced alkylated product was converted to 3S univalent components. After digestion with papain, gel filtration on 'Sephadex G-25' again revealed the two peptide fractions corresponding to those obtained before: fraction A with 35 per cent and fraction B with 50 per cent of the total protein bound radioactivity (Fig. 2).

The principal radioactive peptide in fraction B, however, was not the expected pentapeptide but an overlapping hexapeptide, Cys-Pro-Pro-Pro-Glu-Leu. Furthermore, carboxypeptidase A released leucine and no other amino-acid from the COOH-terminus not only of this peptide but also from $F(ab')_2$ itself. These results suggest some conclusions about the sites in whole IgG attacked by papain and by pepsin. One site of pepsin cleavage is clearly the carboxyl group of the leucine situated five residues from the reactive disulphide bridge: this leucine must form the COOH-terminus of the H chain in $F(ab')_2$. The sites of papain cleavage, on the other hand, can include the NH_2 group of the reactive cystine and the COOH group of glutamic acid situated four residues away (Fig. 1).

Fraction A, liberated by papain from reduced, carboxymethylated Fab', was found to contain a mixture of overlapping peptides:

in this fraction, and by the quantitative and concomitant disappearance of both threonine and galactosamine on mild alkaline hydrolysis^a.

The peptides of fraction A showed no further cleavage by the action of trypsin, papain, pepsin, pronase or subtilisin. In particular, extensive treatment of fraction A with papain failed to release the labelled peptide of fraction B. On the other hand, no amino-sugar was present in the unlabelled peptides isolated from fraction B, which were derived from the region on the NH2 side of Cys-Pro-Pro-Pro-Glu. The resistance of fraction A peptides to enzyme degradation was therefore attributed to the presence of the carbohydrate C₁ situated at a site that otherwise would be susceptible. Furthermore, quantitative analysis of IgG and F(ab')₂ showed that only 35 per cent of the H chains carry a galactosamine residue. Thus two classes of H chain are recognized: one with galactosamine next to the reactive disulphide bridge, the other devoid of galactosamine. These results provide a molecular basis for a recent observation that IgG appears to contain two species which differ in their sensitivity to papain digestion. The suggestion that carbohydrate might influence the pattern of enzyme attack has previously been used to account for a restricted cleavage of IgG, which occurs during limited digestion by papain^{8,8}.

Analyses of hexosamines in whole IgG, F(ab')2, and Fc isolated after a long period of digestion4 reveal at least two carbohydrate moieties (Fig. 3): galactosamine principally on one side of a disulphide bridge in the hinge region and glucosamine on the other, consistent with a previous view of two separate carbohydrate groups, C1 and C2, along the H chain 10,11. The mode of attachment of the galactosamine, coupled glycosidically to the OH group of threonine, contrasts with that of the glucosamine in Fc, which is linked through the β-COOH group of aspartic acid residue¹² (position 150 in ref. 13). The observation that differing sites and linkages are involved in the attachment of two carbohydrates to a single polypeptide chain is relevant to the problems of attachment of the carbohydrate during biosynthesis. That galactosamine is present on only 35 per cent of the H chains raises the interesting possibility that its attachment might be asymmetric in 70 per cent of the four-chain IgG molecules, the remaining 30 per cent being devoid of this carbohydrate side chain.

The unusual composition of the hinge peptide Cys-Pro-Pro-Pro-Glu allows this peptide to be assigned to the NH₂ terminus of the Fe fragment, according to a provisional sequence proposed by Hill et al.¹³. Indeed, the Fe fragment obtained by brief digestion with papain retains the cysteine from a reactive disulphide bridge¹⁴ and we have observed that further digestion of this frag.

The carbohydrate group, C_1 , which contained a single residue of galactosamine, was attached glycosidically to the OH group of a threonine residue preceding the labelled cysteine. All fraction A peptides possess this carbohydrate group; this was shown by the presence of one galactosamine residue per mole of glutamic acid

ment liberates the hinge peptides. These peptides must, therefore, form the link between the Fd and Fc sections of the H chain.

The occurrence of three prolines in a row is unique among proteins of known structure. In view of the striking physical properties of synthetic polyprolyl peptides16 and of the role of proline in forming "corners" in the steric structure of a crystalline protein16, the hinge peptide linking the Fd section to the Fc section of the H chain may well form an essential element in the structure of immunoglobulin. Whether the reactive half cystine residue in the hinge region is coupled to the corresponding half cystine on the complementary H chain or whether this disulphide bridge connects two regions along the same H chain is still undecided. The ease of reduction of this disulphide would generally be taken as evidence in favour of its assignment as an interchain bridge. The isolation of hinge peptides containing the disulphide bridges intact, which will allow their unequivocal assignment, is in progress.

We thank Dr David Givol of the Weizmann Institute for discussing with us our mutual results. One of us (S. U.) thanks the Wellcome Trust for support by a Wellcome research fellowship.

5-Hydroxytryptamine in the Circulation of the Dog

D. P. THOMAS* J. R. VANE

Department of Pharmacology, Institute of Basic Medical Sciences, Royal College of Surgeons of England Estimation of the relative importance of platelets, lungs, liver and peripheral vascular beds in removing this amine from the circulation of the dog shows that the lungs are most active in this respect, and can remove more than 90 per cent in one circulation. This removal does not depend on monoamineoxidase activity.

5-HYDROXYTRYPTAMINE can be removed from the blood in several ways. Platelets1 and erythrocytes2 take it up by a mechanism which, for platelets, has been extensively studied in vitro3,4. Although it has sometimes been assumed that, in vivo, the rapid removal of 5-hydroxytryptamine from the blood is through platelet uptake⁵, there is little evidence for this. Another mechanism by which this amine can be removed was first observed by Starling and Verney⁶. They noted that the vasoconstrictor activity of shed blood, later shown to be caused by 5-hydroxytryptamine, could be removed by perfusing blood through the lungs of a dog. More recent works, has confirmed this observation. Another organ which removes 5-hydroxytryptamine is the liver and it has been shown that 30-80 per cent of 5-hydroxytryptamine injected into the portal vein disappears in its passage through the liver 10.

We have estimated the relative importance of the platelets, the lungs, the liver and the peripheral vascular beds in the removal of 5-hydroxytryptamine from the circulating plasma of dogs. 5-Hydroxytryptamine was assayed continuously by the blood bathed organ technique11. The assay organs were rat stomach strips¹², which contracted to 5-hydroxytryptamine, and a rat colon¹³, which did not, but instead responded to angiotensin or prostaglandins. While the dog was being prepared the assay organs were suspended in polypropylene chambers and superfused14 in series with Krebs solution. The movements of the organs were recorded on a Beckman Offner 8 channel dynograph with 'Ether' strain gauges attached to auxotonic 15 levers; the initial load was 1-3 g. In some experiments two banks of assay organs were prepared so that the concentrations of 5-hydroxytryptamine in venous and arterial blood could be assayed simultaneously.

Dogs of either sex weighing between 6 and 27 kg were anaesthetized with halothane delivered from a Goldman vaporizer; anaesthesia was then maintained chloralose (100 mg/kg given intravenously) and supple-

* On leave of absence from the Department of Medicine, Tufts University School of Medicine, Boston, Mass.

mented when necessary with pentobarbitone (5-10 mg/kg, given either intramuscularly or intravenously). trachea was cannulated and the lungs were ventilated mechanically. Polyethylene cannulae were tied into a femoral or carotid artery and a femoral or jugular vein for the continuous removal and replacement of blood. Mean arterial blood pressure was recorded on the dynograph from a Statham pressure transducer $(P \ 23Db)$ attached to a side arm of the arterial cannula. Heparin (1,000 IU/kg) was injected intravenously and the assay organs were then superfused at a rate of 10 ml./min with arterial or venous blood delivered by a roller pump. The blood was then collected in a reservoir and returned to the dog either by gravity or by a second channel in the roller Catheters were introduced, as described later, either for the continuous infusion of substances or for the removal of blood for assay. In any one experiment only one carotid artery was occluded and, if two arterial catheters were needed, the other was placed in a femoral The positions of all catheters were confirmed post mortem. Platelet counts were determined by the method of Brecher and Cronkite¹⁶ using phase contrast microscopy.

Inactivation of 5-Hydroxytryptamine in Circulating Blood

The inactivation of 5-hydroxytryptamine by blood was measured by passing the blood through a length of silicone tubing of 3 mm internal bore and 45 ml. capacity immersed in a water bath maintained at 37° C. The blood first circulated through this incubating circuit and then superfused the assay organs. By infusing 5-hydroxytryptamine at different points in the circuit, the drug was in the blood for known periods of time before reaching the assay tissues. For example, the contractions of the rat stomach strip to the same rate of infusion of 5-hydroxytryptamine incubated in the blood for 15, 30, 60, 120 and 240 sec could be compared with, and bracketed between, the contractions induced by infusions of 5-hydroxytryptamine made close to the tissues. From this the dis-

Table 1. Estimation of the half life $(t_{1/6})$ of 5-hydroxytryptamine (5-ht) in blood

Experiment No.	Initial concentration of 5-HT in blood (ng/ml.)	<i>t</i> _{1/2} (sec)	Platelet count/mm³
1	40	60	153,000
2	10 20 40	60 60 94	112,000
3* * Venous blood	20 40 80 d.	60 100 120	166,000

appearance and the half life could be calculated. A diagram of the apparatus has already been published¹⁷.

The half life of 5-hydroxytryptamine in circulating blood was estimated seven times in three experiments (Table 1). The concentrations at which the estimates were made depended on the sensitivity of the assay organs. In most experiments, the rat stomach strips detected 2-5 ng/ml. and allowed assay of up to 50 ng/ml. The half life of 5-hydroxytryptamine in either venous or arterial blood was 60 sec at the lower concentrations. In two of the experiments, when the concentration of 5-hydroxytryptamine was raised, the half life also increased to 94 sec in one and to 100 sec in the other. Thus, it seems possible to saturate whatever mechanism it is that removes 5-hydroxytryptamine from blood.

In the present experiments, the count of circulating platelets was only about half the normal, mainly through platelet clumps forming in the return reservoir of the extracorporeal circulation. Despite this relatively low platelet concentration it can be concluded that the disappearance of 5-hydroxytryptamine from the blood, whether it is caused by breakdown or uptake, is too slow a process to account for the very rapid removal of 5-hydroxytryptamine from the circulation.

Disappearance of 5-Hydroxytryptamine in the Portal Circulation

The abdomen was opened in the mid-line and a fine polyethylene catheter was inserted into a tributary of the splenic vein and pushed down until its tip lay in the main portal vein, close to the liver. Infusions were made through this catheter into the portal vein. The amount of 5-hydroxytryptamine which survived passage through the liver was estimated by bathing the assay organs in mixed venous blood (obtained from a catheter advanced down the jugular vein into the right ventricle). contractions of the rat stomach strips which were produced by the intraportal infusions were bracketed between contractions induced by intravenous infusions. In seven experiments (Table 2) more than 70 per cent of the infusions of 5-hydroxytryptamine into the portal circulation disappeared before reaching the heart (mean 75.0 per cent, standard error ± 2.97). A record from one of these experiments is shown in Fig. 1, which shows part of a tracing from an experiment in which one rat stomach

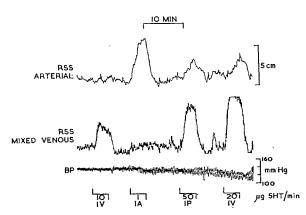

Fig. 1. One rat stomach strip (RSS) was superfused with arterial blood (top record) and another with mixed venous blood (middle record) taken from a 10 kg female dog. Blood pressure is shown on the bottom record. The first response shows the sensitivity of the RSS in venous blood to an infusion of 5-hydroxytryptamine (5-HT, 10 μg/min for 4 min). None of this infusion could be detected in the arterial circulation, despite the high sensitivity of the second RSS which responded to 1 μg/min intra-arterially. An infusion of 5-HT (50 μg/min for 4 min) was then given into the portal vein and, of this, 10-20 μg/min ms detected in the mixed venous blood, and less than 1 μg/min in the arterial blood. Similarly, from the intravenous infusion of 20 μg/min, less than 1 μg/min survived passage through the pulmonary circulation. Time, 10 min. Vertical scales: 5 cm and mm of mercury.

strip was bathed in arterial blood and another in mixed venous blood. An intraportal infusion of 5-hydroxytryptamine (50 μ g/min) induced a contraction of the rat stomach strip in venous blood which was intermediate to those induced by 10 μ g and 20 μ g/min intravenously. The rate of disappearance was remarkably constant from dog to dog. Up to the highest rates of infusion tested (400 μ g/min) the same percentage of the infusion disappeared, showing that the mechanism responsible for removing the amine from the blood was not easily saturated.

Disappearance of 5-Hydroxytryptamine in the Pulmonary Circulation

In these experiments, the assay organs were bathed in arterial blood taken from a catheter in the femoral artery. The effects of intravenous infusions were compared with those of infusions into a catheter in the ascending aorta. In eleven experiments, some of them in the same animals used for estimation of the disappearance of 5-hydroxy-tryptamine from the portal circulation, more than 90 per cent disappeared in one passage through the pulmonary circulation. The amount varied from 80 per cent to 98 per cent with a mean of 92-0 per cent, standard error ± 1.59 . For example, from an infusion of 5-hydroxytryptamine (10 µg/min) intravenously (Fig. 1), so much was removed in the pulmonary circulation that none could be detected in the arterial blood. From an infusion of 20 µg/min intravenously, less than 1 µg/min (<5 per cent) reached the arterial circulation.

Inhibition of Monoamineoxidase Activity

In three experiments, a monoamineoxidase inhibitor (nialamide, 20 mg/kg) was injected intravenously, after the disappearance of 5-hydroxytryptamine in the portal and pulmonary circulations had already been estimated. After 1 h, the removal of 5-hydroxytryptamine by the portal (one experiment) and pulmonary (three experiments) vascular beds was re-estimated. There was no change in the percentage removal of 5-hydroxytryptamine either in the liver or in the lungs (Table 2). To make sure that the enzyme inhibitor had sufficient time to have a maximum effect, three other dogs were treated with a long-lasting inhibitor, mebanazine, in a dose (7 mg/kg subcutaneously) which gave more than 95 per cent inhibition of rat liver and rat brain monoamineoxidase¹⁸.

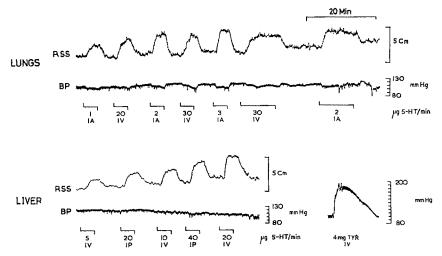

Fig. 2. The dog (12.5 kg male) was pretreated with mebanazine, as described in the text. First (upper tracing) the rat stomach strip (RSS) was superfused with arterial blood to estimate removal of 5-hydroxytryptamine (5-HT) by the lungs. From intravenous infusions (IV) of 20-30 ug/min, more than 1 μ_B and less than 3 μ_B /min were detected in the arterial blood. Later, an infusion of 80 μ_B /min was given intravenously for 10 min. From this, about 2 μ_B /min was detected in the arterial circulation. The RSS was then superfused with mixed venous blood (lower tracing) and infusions of 5-HT into the portal vein (IP) compared with intravenous infusions (IV). From 20 μ_B /min (IP) about 17 μ_B /min survived and from 40 μ_B /min (IP) about 15 μ_B /min came through the portal circulation. The last tracing shows the blood pressure response to tyramine (4 mg TYR IV). Compared with untreated dogs, the rise in blood pressure was greatly prolonged, showing that the amine oxidase inhibitor had been effective. Time 20 min; vertical scales in 5 cm and mm of mercury.

The injection was repeated on the second day and the animals taken for experiment on the third. The disappearance of 5-hydroxytryptamine in the liver and the lungs of these three animals was in the same range as in the untreated animals (Table 2).

An example is shown in Fig. 2, which is taken from an experiment in which the dog had been pretreated with mebanazine for 2 days. The assay organs were first superfused with arterial blood to estimate the disappearance of 5-hydroxytryptamine in the pulmonary circulation. During an intravenous infusion of 20 µg/min. only 1.5 µg/min was detected in the arterial circulation, and during an infusion of 30 μ g/min only about 2 μ g/min survived. This tracing also shows that the removal of 5-hydroxytryptamine was constant, even when the infusion was maintained for 10 min. The assay tissues were then bathed in mixed venous blood so that the disappearance of 5-hydroxytryptamine in the portal circulation could be determined. During an infusion of 20 µg/min into the portal vein, only about 7 µg/min was detected in the mixed venous blood and, during an infusion of 40 µg/min was detected in the mixed venous blood and, during an infusion of 40 µg/min was detected in the mixed venous blood and, during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected in the mixed venous blood and during an infusion of 40 µg/min was detected min, about 15 µg/min. Finally, an injection of tyramine (4 mg) was given intravenously. The effect on the blood pressure was greatly prolonged, taking more than 10 min to return to baseline, compared with a return within 3-5 min in untreated dogs. This prolongation of the action of tyramine shows that the amine oxidase had been effectively inhibited by pretreatment of the dog with me banazine.

Disappearance of 5-Hydroxytryptamine in Peripheral Vascular Beds

For these experiments the assay organs were bathed in mixed venous blood taken from the right ventricle. A catheter was also inserted into the exposed right carotid artery and advanced retrogradely until its tip was in the left ventricle, as shown by the pulse pressure recorded through it. The catheter was then withdrawn until the tip was in the ascending aorta, just above the aortic valves. Infusions through this catheter into the total cardiac output were compared for their effects on the assay organs with intravenous infusions. Thus, the 5-hydroxytryptamine which disappeared in one passage through the peripheral vascular beds was estimated. In one experiment 30 per cent disappeared, and in another 60 per cent.

Several conclusions can be drawn from these experiments. First, removal of 5-hydroxytryptamine by enzymes or cells in the blood is not sufficiently fast to account for its almost immediate disappearance from the circulation. In the few seconds that it takes blood to pass through the portal circulation, more than 70 per cent of the 5-hydroxytryptamine disappeared and, in the pulmonary circulation, more than 90 per cent. The pulmonary circulation takes the whole of the cardiac output, and so the lungs are presumably the chief site for the clearance of 5-hydroxytryptamine, and are much more effective than the peripheral vascular beds. The fact that we found a greater rate of removal of 5-hydroxytryptamine in the lungs than reported previously8,9 may be because injections temporarily swamp the removal mechanism, allowing more to escape. We used infusions and waited for equilibrium conditions to be established.

5-Hydroxytryptamine is released into the circulation in the carcinoid syndrome¹⁹ and has also been implicated in the dumping syndrome²⁰. 5-Hydroxytryptamine is released from the isolated perfused dog intestine by various drugs and by muscular contraction21,22. the intestine is probably the most important site of release of 5-hydroxytryptamine into the blood stream. The fact that the portal and pulmonary circulations together diminish the concentration of any 5-hydroxytryptamine in the portal blood by more than 99 per cent suggests a protective mechanism which prevents the amine from reaching the arterial circulation where it may have dramatic cardiovascular effects. It may also explain why increased concentrations of 5-hydroxytryptamine in peripheral blood during dumping in dogs have not been observed despite increased 5-hydroxytryptamine concentrations in venous blood draining the small intestine23,24. The specificity of the mechanism is shown by the much lower disappearance in the peripheral vascular beds and by the fact that other amines, such as adrenaline, pass through the pulmonary circulation without loss (unpublished results of Ginn and Vane).

What process is responsible for the disappearance of 5-hydroxytryptamine in the liver and the lungs? The amine is not lipid soluble and does not easily penetrate cell membranes²⁵, unless by a special transport mechanism. If it is entering cells, they probably do not contain amine oxidase, because inhibition of the enzyme did not change the amount of 5-hydroxytryptamine disappearing.

Radioactive techniques have shown that 5-hydroxytryptamine is specifically taken up into reticular endothelial cells in the liver and into septal cells in the lungs26, neither type of cell containing monoamineoxidase(personal communication from M. D. Gershon). It is possible that 5-hydroxytryptamine is metabolized by some other enzyme, or that it is stored, to be metabolized later at a slower rate. If storage is involved, the capacity of the stores must be enormous, for in some experiments the dog's lungs were removing about 100 μ g/min or 2 mg in a 20 min infusion. Experiments with labelled 5-hydroxytryptamine, used in conjunction with the present technique, should answer this point.

It is possible that 5-hydroxytryptamine is immediately taken up by, or gradually transferred to, platelets trapped in the lungs. Virtually all the 5-hydroxytryptamine in the blood is normally contained within the platelets. It has been calculated that from 20 to 50 per cent of the mature megakaryocyte population ultimately reaches the lungs, and that in man 7-17 per cent of the platelets are released in the pulmonary capillaries27. The lung capillaries are therefore a rich source of platelets, although it appears unlikely that they alone are sufficient to account for the very rapid disappearance of circulating 5-hydroxy-

tryptamine.

In many species, 5-hydroxytryptamine causes constriction of the airways when injected intravenously. 5-Hydroxytryptamine released from platelets has also been implicated in the airway constriction that develops in dogs after either pulmonary emboli²⁸ or administration of bacterial endotoxin²⁹. Little or no 5-hydroxytryptamine survives passage through the pulmonary circulation, and so airway constriction after embolization must be caused primarily by changes in the peripheral airways, which are perfused by the pulmonary circulation, and not the conducting airways, which are perfused by the bronchial circulation³⁰.

We thank Mr R. Ginn and Mr R. Flower for technical assistance, the Medical Research Council for a grant, and ICI (Pharmaceutical Division) for mebanazine. work was also supported in part by a grant from the US Public Health Service.

"Pre-imaginal Conditioning" in Drosophila

Ьy AUBREY MANNING Department of Zoology, University of Edinburgh

Drosophila reared on a medium containing geraniol showed reduced aversion to its odour when adult. Experiments show that this change is caused by a form of habituation and is not associative learning.

ATTEMPTS to demonstrate associative learning of any sort in the Diptera have met with little success and the only convincing report is that of Murphey1. However, flies and particularly *Drosophila* are very convenient experimental animals and any demonstration of conditioning opens up exciting prospects for the study of genetic effects on learning. Accordingly the recent claim of Hershberger and Smith to have demonstrated classical conditioning in *Drosophila* is of considerable importance². Their work makes use of the remarkable phenomenon first described by Thorpe³ and which he called "preimaginal conditioning".

Drosophila which have been reared normally are aversive to the smell of peppermint, but flies which have been reared in a medium containing 0.5 per cent peppermint oil show greatly reduced aversion. Thorpe showed conclusively that exposure to peppermint during the larval period alone was sufficient to change the behaviour of adults. While Thorpe originally interpreted these results in terms of conditioning, he later suggested that the change is due to a form of habituation which persists through the pupal stage.

Hershberger and Smith using a similar technique have been able to confirm almost all of Thorpe's results, but they disagree with his interpretation. They point out that in every case where a population of flies shows reduced aversiveness to peppermint, this smell had previously been associated with food, and they conclude that the changed behaviour of flies reared in peppermint medium is caused by positive conditioning to the smell, not to habituation.

One may reasonably question whether the evidence presented by Hershberger and Smith or by Thorpe is adequate to prove their conclusions. In neither case were the responses of individual flies tested on a second or subsequent occasion to obtain some measure of the consistency of their response, and this is crucial for deciding between the two hypotheses.

The experiments reported here were begun in an attempt to change the levels of pre-imaginal conditioning by selection and to look for genetic assimilation of the acquired trait, along the lines explored by Moray and Connolly. The results will be published in detail elsewhere, but as far as the general nature of the phenomenon is concerned,

they confirm those of Thorpe. Geraniol was used as a conditioning scent in preference to peppermint oil because it is a pure substance, not a mixture. It has a strong, sweet smell which when dilute is mildly attractive to the flies, but at the concentrations used in the tests some 80-90 per cent of normally reared flies show aversion.

A simple Y tube olfactometer was used, very similar to that used by Hershberger and Smith, and the general procedure was also similar. Groups of between ten and thirty flies of one sex were let into the Y tube through which a slow current of air was drawn. Flies could be collected from a small chamber attached to each arm of the Y after having made their "choice". One arm was "baited" with two small drops of geraniol placed upstream of the air intake to the collecting chamber; the scented arm changed sides at random between tests.

Flies were reared on a normal medium of agar, corn meal and molasses or on this medium with 0.5 per cent geraniol by volume added just before pouring into culture bottles. Adult flies were collected within a few hours of hatching and kept in groups of twenty to twentyfive in 3×1 in. vials containing normal, unscented medium. Before every test they were starved for 5-6 h in vials providing only water on cotton wool.

Table 1. Numbers of flies going to geraniol and blank arms of olyactometer after normal rearing (A) and rearing in geraniol medium (B), together with second run of geraniol-reared flies that went to GERANIOL ARM ON FIRST RUN (C)

		A			В		. σ				
	Flies r	eared no	rmally		rnes rea First ru		geraniol-medium Second run of flies going to geraniol on first run				
Gener-	Ger-		%	Ger-		%	Ger-		%		
ation	aniol	Blank	blank	aniol	Blank	blank	aniol	Blank	blank		
1	4	48	92.3	30	26	46.4	14	9	39.1		
3	_	_	_	120	103	46.2	58	55	48.7		
3				118	108	47.8	58	48	45.8		
4 5	5	53	91.4	64	123	65.8	25	39	60.9		
5	11	51	82.3	70	42	37.5	30	30	50.0		
6	8	32	80.0	57	96	62.7	27	30	52.6		
7	3	47	94.0	43	77	64.2	20	23	53-5		
8	7	45	86.5	109	123	53.0	53	49	48.0		
Total	38	276	87.9	611	698	53.3	285	283	49.8		

Table 1 (columns A and B) gives the results of a series of tests made on successive generations of flies bred normally and on geraniol medium. Although there is some variability—and olfactometers of this type are far from exact instruments—the difference between the two groups is consistent and striking. The mean "aversiveness" of the former is 87.9 per cent, but rearing in the presence of geraniol reduces this to 53.3 per cent.

Each test provided a group of flies which, having been reared in the presence of geraniol, "chose" to move toward this scent when moderately food deprived. The most critical test of positive conditioning versus habituation is to run these flies through the olfactometer a second time. Ignoring "accidental choices", on the habituation hypothesis one supposes that turning towards geraniol on the first trial represents only random choice and that such flies will segregate at random between geraniol and blank on the second run also. According to the conditioning hypothesis most flies choosing geraniol on the first run do so because they associate its smell with food and there should be an increased proportion of choices to geraniol on the second run.

The results of the second runs are also shown in Table 1 (column C) and they strongly support the habituation hypothesis, for in no case did the proportion of flies

Table 2. First and second runs of geraniol-reared flies "rewarded" for going to geraniol on first run

	First	t run			run of file	s going to Arst run
Group	Geraniol	Blank	% blank	Geraniol	Blank	% blank
1	31	38	55.1	13	16	55.1
2	64	100	60-9	30	29	49-1
3	60	102	62-9	18	34	65.4
Total	155	240	60-7	61	79	58-4

Table 3. Segregation in olfactometer of flies reared normally or on geraniol medium kept for 18 h before testing in scented or unscented vials

	Normal	ly reared	Geraniol reared		
	Scented vials	Unscented vials	Scented vials	Unscented vials	
Going to geraniol	81	45	55	38	
Going to blank	34	58	33	38	
Per cent blank	29.5	56-3	37.5	50∙0	

going to each arm differ significantly from random choice, using the x2 test.

"Rewarding" flies for choosing geraniol has no effect on their subsequent choice. Table 2 gives the results from three groups of flies which were allowed to feed on sucrose in the collecting chamber if they chose the geraniol arm on their first run. On the second run these flies also segregated at random in two of the groups; in the third run, segregation is significantly different from random, but in the opposite direction to that predicted by the conditioning hypothesis, that is, fewer flies "chose" geraniol. Possibly the concentration of geraniol was higher on the second run than on the first.

The results of two more experiments serve to reinforce the habituation hypothesis. First, an attempt was made to "counter-condition" adults by associating scent with food deprivation. Normal and geraniol-reared flies were confined on hatching in vials containing water soaked cotton wool. Half the vials in each group were scented with geraniol. When tested in the olfactometer 18 h later, both groups which had been starved in the presence of geraniol showed reduced aversiveness (Table 3), although only in the case of normal reared flies was this reduction significant ($\chi^2 = 15.93$). This result disagrees with that obtained by Hershberger and Smith2, but suggests that habituation also occurs in adult flies as well as larvae.

Second, one may consider the behaviour of flies which go to the blank arm of the olfactometer on the first run. The habituation hypothesis supposes that those flies which go to the scented arm represent approximately 50 per cent of that proportion from the total population which has been rendered insensitive to geraniol, the other 50 per cent will go to the blank arm. The proportion of habituated flies will vary for a number of reasons, but if we consider those cases in which less than half the flies go to geraniol on the first run, then, ignoring "accidental" choices, the preponderance of flies choosing the blank arm should represent that proportion of the population which has not become habituated and remains aversive to geraniol. If the number of flies going to the scented arm on trial one is x and that to the blank y, then y-x flies are aversive and should continue to avoid the scent on the second run. If the flies choosing the blank arm are given a second trial they should segregate with x/2 + (y-x)going to the blank arm.

The population recorded in Table 1 was not tested in this way, but data are available from another population being selectively bred for aversiveness, that is, for a reduced response to rearing in geraniol medium. In most generations less than 40 per cent of flies from this line go to the scented arm on the first run. Table 4 shows the results of tests on several successive generations and compares the actual segregation observed on the second run of flies "choosing" the blank arm on the first run with that which would be predicted using the formula given

Table 4. SEGREGATION ON FIRST RUN OF GERANIOL REARED FLICS AND SECOND RUN OF FLIES GOING TO BLANK ON FIRST RUN

DATON OF THE									
First run				Second	Second run of flies going to blank on first run				
Genera- tion	Ger- aniol	Blank	% blank	Ger- aniol	Blank	% blank	Predicted % blank

The predicted segregation on the second run, based on the habituation hypothesis, is also shown.

above. In no case does the observed result differ significantly from the predicted one.

These experiments all suggest that Thorpe's interpretation is correct and that "pre-imaginal conditioning" is a form of habituation. Crombie's thorough work with blowflies, although somewhat different in procedure, also supports this conclusion. The physiological basis for this habituation remains quite obscure, although it seems unlikely to be caused by peripheral changes alone. The pupal stage in Diptera involves a great deal of breakdown and reconstruction of the body and sense organs, but the central nervous system is less affected.

Because most flies become habituated when reared in geraniol medium it is difficult to "improve" this response by selection. In most cases, however, a small proportion of flies seems to be unaffected by exposure and remains genuinely aversive. Preliminary results suggest that the difference between habituated and aversive flies is partly genetic and that the proportion of aversive flies can be increased by selection. Further tests on selected lines should help to clarify the basis of habituation.

I thank Miss M. C. Hill for her help and Miss F. Wedlock for permission to quote from some of her unpublished work. The Science Research Council gave financial support.

Establishment of a Lunar Unipolar Generator and Associated Shock and Wake by the Solar Wind

by
C. P. SONETT
D. S. COLBURN
Space Sciences Division,
Ames Research Center,
NASA, Moffett Field,
California

The impact of the solar wind on a dynamo- and atmosphere-free body such as the Moon generates two distinguishable current systems denoted as Cowling $(\dot{B}\neq 0)$ and unipolar $(\dot{B}=0)$. The unipolar system representing the steady state must close through the neighbouring plasma and thus has the form of a simple linear unipolar generator. The relationship of the current to the conductivity of the body is investigated for the homogeneous and the radially inhomogeneous Moon. The current density is determined by the power flow in the solar wind and the conductivity of the body. The fundamental equation for the interior potential associated with the unipolar generator is solved for a special case.

Gold's suggested that the impact of the solar wind on the Moon would cause a captured magnetosphere and an accompanying shock wave. An additional consequence of the model was the formation of a poloidal magnetic field, which might masquerade as a dynamo field. In Gold's model the plasma contacted the surface and was wholly absorbed, neutralized, and re-emitted at the characteristic thermal state of the surface matter. The electrodynamics of interaction was described by a diffusion time required for field lines to transit the interior and emerge on the antisolar side where pinching off with an x-null geometry could take place. The characteristic time was given by

$$\tau = \mu \sigma L^2 \tag{1}$$

where τ is the Cowling² decay time, μ and σ the magnetic permeability and bulk electrical conductivity, respectively, and L the scale size (lunar diameter). More recently, Tozer and Wilson³ considered a similar model (compare Neugebauer⁴).

From examination of interplanetary monitoring platform I data, Ness⁵ suggested the formation of a lunar wake. Greenstadt⁶ and Hirshberg⁷, criticizing this suggestion, pointed out that the interplanetary medium was disturbed at the time of the observations and the certainty of the observations remains unclear (compare Ness⁸, Michel⁹). Gringauz et al.¹⁰ and Dolginov et al.¹¹ reported the existence of a sunward zone of interaction before the Moon. Ness suggested that the Moon was immersed in the Earth's magnetic tail during these observations. Finally, at least some of Gold's conclusions can be shown to arise from an excessive decay time attributable to a product, μσ, about 10⁶ larger than probable estimates for a lunar interior.

Additional work on this problem has been carried out by Dessler¹², who investigated the interaction with an atmospheric planet (Mars) with an ionosphere generated partly by the interaction. Michel¹³ has discussed the lunar atmosphere with magneto-hydrodynamic interaction. His calculations are approximations, for the supersonic case is not explicitly formulated and the motional electric field used does not account for a deviation of the flow to the limbs of the Moon.

Our purpose is to point out that the relative motion of the Moon with respect to the interplanetary plasma fulfils the essential requirements for a simple unipolar generator of linear geometry where the Moon is envisaged as a bar moving along a set of rails threaded by magnetic flux. This is the simplest type of unipolar generator (compare Panofsky and Phillips¹⁴; Cullwick¹⁵). Rotation of the Moon with respect to the Sun during its lunation is ignored. Application of Maxwell's equations permits certain very general statements to be made regarding the details of the interaction problem. The magnetohydrodynamic flow field cannot influence these results fundamentally. The plasma flow does modify the symmetry of the problem, and the flow deviation for strong interaction causes a decrease in the net induction in the Moon. In a very approximate way, to demonstrate the saturation process, we employ a coefficient of loss, k, for the plasma swept to the limbs of the Moon which also carries with it magnetic field. Thus the net unipolar electric field in the interior is reduced by the factor (1-k). This is discussed later to account for lessened induction.

For non-homogeneous bodies such as a hot Moon, it is probable that the electrical conductivity of the interior is a strong function of radius. In this case the

electric potential in the interior is radically altered from the homogeneous case and therefore the most resistive layer will dominate the current system. This means that a thin high impedance surface layer can quench the unipolar induction currents.

The principle of unipolar induction permits the electric field in the interior to be calculated. An equivalence to magneto-hydrodynamic diffusion has been shown by Sonett and Colburn in unpublished work. The diffusion of field in the Moon is not magneto-hydrodynamic, because it does not involve a fluid or deformable conductor. The process might be thought of as being caused by eddy currents, but this is conceptually misleading because, in the steady state, Maxwell's equations imply deformable conductors for induction fields. This difficulty is eliminated when the model using a unipolar generator is employed, with the current paths steady and closing in the plasma. For the steady state magnetic field, and consequently curl-free electric field, it is not possible for current streamlines to close in the Moon.

There are two current systems resulting from the interaction of the Moon with the solar wind. Consequently, all local perturbation fields have two distinguishable sources. In our model, the electric field excited in the Moon, which drives the current system, is either curl-free when the relevant solar-wind-driving parameters are time stationary or results from induction when $\dot{B}\neq 0$. We shall deal only with the steady state $(\dot{B}=0)$, and demonstrate that the mechanism is that of a unipolar generator. For the Moon, the diffusion time is sufficiently short compared with observed interplanetary sector structure to allow steady state conditions to be significant.

In the following the Gold mechanism is assumed to be applicable—that is, any plasma coming into contact with the surface of the Moon is adsorbed in the surface matter, electrically neutralized by electron pick-up, and eventually released into the lunar atmosphere thermally. Consider a solar wind with velocity, v, and a magnetic field, B, both independent of time. Then, in a frame of reference at rest with respect to the Moon, the motional electric field,

$$\mathbf{E}_m = \mathbf{v} \times \mathbf{B} \tag{2}$$

and everywhere $\dot{\mathbf{B}} = -\nabla \times \mathbf{E} = 0$. A body such as the Moon, when subjected to this field, becomes electrically polarized where $\mathbf{E}_p(t)$ is the field at time, t, that is,

$$\mathbf{E}_{p}(t) = [1 - e^{-(\sigma/\varepsilon)t}] \mathbf{E}_{p_{0}}$$
(3)

where \mathbf{E}_{p_0} is the final polarization field, ϵ , the specific inductive capacity, and

$$\tau = \epsilon/\sigma$$
 (4

the time constant for the placement of polarization charges. When conductive electrical contact between the Moon and the plasma is forbidden, for example when the Moon possesses an outer shell of extreme resistivity

$$\mathbf{E}_m + \mathbf{E}_p = 0 \tag{5}$$

the charges have a dipolar distribution and, for a homogeneous Moon, are all deposited on the surface. The field is electrostatically identical to that of a sphere in a uniform external electric field. In this limit there can be no interior current system, field lines are severed at the surface, and, other than the formation of a plasma cavity in the neighbourhood of the antisolar hemisphere, no interaction is observed. This statement implies the validity of the Gold mechanism and in the context of magneto-hydrodynamics is equivalent to the loss of individual identity of field lines in the interior. An alternative statement would be that field still diffuses through the Moon, but there is no way to identify the motion in the interior.

When the Moon is in conductive contact with the solar wind, polarization charges leak into the plasma and establish an externally closed current system and a perturbation magnetic field. The system constitutes a linear unipolar generator; the solar wind supplies the brushes. The charge carriers required in the plasma can easily be supplied by photoelectrons (unpublished work of the Project Tycho Study Group of the University of Minnesota), but they destroy the cylindrical symmetry.

The process is naturally limited by the tendency for plasma and field to slip around the flanks of the Moon when the unipolar magnetic field grows large. An approximate idea of this limiting process is given by balancing the solar wind pressure in the plane normal to the ecliptic and containing the Moon-Sun line against the unipolar field pressure. Both pressures will vary over the face of the Moon. That part of the deviated flow caused by the formation of back pressure from the unipolar field must be excluded in the calculation of the interior electric field. The fraction, k, of plasma carried to the sides has frozen in field which is also carried to the limbs. Thus the interior electric field must be decreased by the factor (1-k). Then the interior current density, $\mathbf{j} = (1-k)\sigma \mathbf{E}_m$ where \mathbf{E}_m is the electric field which would develop for no interaction. The total current depends on latitude. The total current at latitude, θ , is given by

$$I = jA(\theta) = j\pi r^2 \cos^2 \theta = (1 - k)\sigma E_m \pi r^2 \cos^2 \theta$$

where r is the lunar radius. The unipolar field at latitude θ is calculated from the circuital theorem

$$B = \frac{M_0 I}{2\pi r \cos \theta} = \frac{M_0 (1 - k) \sigma E_m r \cos \theta}{2}$$

and the pressure of the unipolar field is

$$p_{B} = \frac{B^{2}}{2M_{0}} = \frac{M_{0}(1-k)^{2}\sigma^{2}|E_{m}|^{2}r^{2}\cos^{2}\theta}{8}$$

This is balanced against the plasma pressure so that

$$\frac{k}{(1-k)^2} = \frac{\mu \sigma^2 |E_m|^2 r^2}{8nmv^2} \tag{6}$$

where k is the loss factor of electric field; E_m is the freestream motion field; $M = M_0$ and σ is the constitutive parameters of the Moon, as before; r is the lunar radius, and n, m and v are the parameters of the free-stream solar wind. The assumption is made that the unipolar field pressure at latitude 0 depends on the current flowing through the cross-sectional area for that latitude as if it were a cylindrical conductor of infinite length. introduces some error into the approximation. there is no account taken of the decrease in plasma pressure with longitude. In the present calculation of the unipolar field the pressure does not decrease with longitude. Thus there is here involved an additional approximation from the exact case. The values of k shown in Fig. 1 are reasonable approximations in the solar meridian plane for a homogeneous Moon. In equation (6) the solar wind pressure varies as cos² θ in the meridian plane where 0 is the latitude, while the current density and, consequently, the unipolar fields vary as $\cos \theta$. Consequently, polar dependence disappears from equation (6).

Values of k shown in Fig. 1 indicate that, for typical interplanetary magnetic fields, $10^{-6} \le \sigma \le 10^{-3}$ mho/m represents the transitional values of conductivity in going from weak to strong interaction, with the formation of a magnetosheath and the development of a shock wave. The ultimate source of work to drive the dynamo is determined by the solar wind power flow, also indicated in Fig. 1.

There must exist in addition the effect of terminating the plasma flow against the surface of the Moon. Because of the intrinsic diamagnetism of the plasma, a field jump can be expected at the surface, but the amount of the jump depends on the net surface currents. If the Moon were a perfect reflecting wall the field jump would not appear because the net surface current due to gyrating protons and electrons would be balanced by an equal

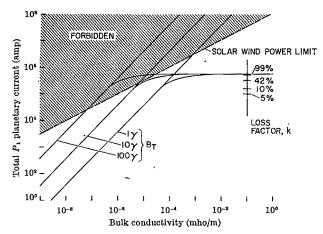

Fig. 1. Approximate total P_1 unipolar planetary current shown as a function of bulk conductivity for a homogeneous Moon. The straight lines are the free-stream tangential magnetic field. They can also represent the motional electric field in the solar wind and the electric field within the Moon in the limit of small interaction and constant v. The saturation caused by a unipolar field comparable with the solar wind field is shown to take place in the range $10^{-6} \leqslant o \leqslant 10^{-3}$ mho/m for typical values of the interplanetary magnetic field. The solar wind power flux, including the particle contribution for v = 400 km/sec and n = 5 cm⁻³ over a target area of lunar radius, determines the ultimate limit of available work for driving the unipolar current system. The loss factor, k, is shown on the right ordinate. The expectation that the Moon has a relatively cool insulating outer layer reduces the current by at least an order of magnitude from the homogeneous case.

current created by reflected particles¹⁶. For subsonic flow against the surface the Gold mechanism, which inhibits reflexion, would allow the field jump to appear, but for supersonic impact, only the electrons will have fast enough orbital velocity to contribute to the surface currents. We have not included the diamagnetic effect in the calculations, but it should be included in a more exact model.

We need here to clarify an important conceptual point. The transformation from the moving frame of the solar wind, where no electric fields are permitted because of the high conductivity, to another frame must be generally accompanied by the placement of polarization charge layers if there is a conducting body at rest in the new frame. E_m is strictly a property of the Galilean transformation and by itself cannot determine the electric fields in a configuration. Polarization charges are consequently found on the surface of the Moon in the present model. The assumption in the present model is that the plasma conductivity is always significantly greater than that of the lunar interior or surface layer, so that polarization fields are absent for the homogeneous Moon or present only in the interior when the low surface conductivity limits the current flow. An additional limitation on the current flow is approximated by the k factor, however, for, if plasma and the accompanying frozen-in field lines are deflected around the Moon, the E_m itself is reduced in the lunar interior.

These arguments, developed for a homogeneous Moon, can be generalized to one having a steep thermal and conductivity gradient. The unipolar system is characterized by curl-free electric fields and therefore in the Moon $\nabla \cdot \mathbf{j} = 0$. Because $\mathbf{E} = -\nabla \varphi$ and $\mathbf{j} = \sigma \mathbf{E}$, it follows that $\nabla \cdot (-\sigma \nabla \varphi) = 0$, so that the fundamental equation for the unipolar electric potential in the Moon becomes

$$\sigma \nabla^2 \varphi + \nabla \sigma \cdot \nabla \varphi = 0 \tag{7}$$

Under the constraint that $\sigma = \sigma(r)$ alone, that is, no angular dependence, equation (7) is separable. We define the potential as $\varphi(r,\theta) = R(r)\Theta(\theta)$ so that equation (7) becomes

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2 \frac{\mathrm{d}R}{\mathrm{d}r}\right) + \frac{r^2}{\sigma} \frac{\mathrm{d}R}{\mathrm{d}r} \frac{\mathrm{d}\sigma}{\mathrm{d}r} - n(n+1)R = 0 \qquad (8a)$$

$$\frac{\mathrm{d}}{\mathrm{d}\mu} \left[(1 - \mu^2) \frac{\mathrm{d}\Theta}{\mathrm{d}\mu} \right] + n(n+1)\Theta = 0 \tag{8b}$$

where $\mu = \cos \theta$. Solutions to equations (8) are given by

$$\varphi(r,\theta) = \sum_{n=1}^{\infty} A_n R_n(r) P_n(\cos \theta)$$
 (9) where P_n is the Legendre polynomial of order $n = 1, 3, 5 \dots$

where P_n is the Legendre polynomial of order $n=1,3,5\ldots(2n+1)\ldots$ (The existence of only odd order solutions is a consequence of the intrinsic antisymmetry of the electric field for which only odd order angular solutions are valid.) The boundary conditions are imposed at the surface, that is, $R_n(r)=1$ and $\sigma(r)=\sigma(r_1)$ at $r=r_1$. For the case of uniform lunar conductivity and negligible plasma resistivity the boundary conditions are satisfied by the P_1 current system alone, but other profiles introduce higher orders. The electric field for the P_1 current system is shown in Fig. 2 for a nominal radiogenic, convective lunar interior with a boundary condition imposed on temperature. The bulk conductivity through the interior is calculated from the thermal dependence of olivine P_1 .

The P_1 current system solution of Fig. 2 is given in order to demonstrate that a strong angular dependence exists and that the largest potential drop is restricted to the cool manticular mantle. These conclusions are expected to hold for the complete solution. For $\sigma=$ constant, equation (7) reduces to Laplace's equation with uniform current density. The result that the potential appears primarily across the most resistive part of the unipolar circuit is consistent with circuit theory. The assumption that the solar wind conductivity is higher by orders than that of the Moon means that the magnitude of the electric current is determined by the latter.

The more general case with axial dependence has not been solved because of complications with the current carrier system. For example, if photoelectrons are the primary carriers, then currents can flow only on the sunlit hemisphere. A current model of this type will introduce zonal harmonic dependence, but equation (7) is still separable, and therefore the zonal dependence is multiplicative and the radial and polar dependences of equations (8b) and (9) are valid. The primary limit to

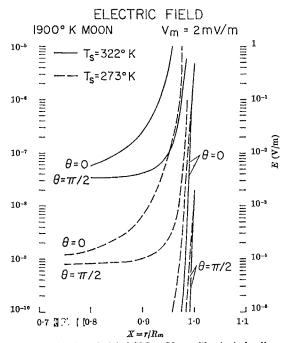

Fig. 2. The planetary electric field for a Moon with a typical radiogenic thermal profile with convection (Model 7 of Fricker et al. ''). The customary thermal profile is modified by specifying the surface temperature, which defines the surface conductivity, one of the boundary conditions for equations (8). The distance scale is normalized to the lunar radius. A strong polar dependence of the electric field appears, and the radial dependence shows that the bulk of the potential drop is in the first few hundred kilometres beneath the surface. The motional field assumed is 2 mV/m. Other values yield similar results by scaling.

our solution will arise from deviations from the assumption as to the introduction of the interplanetary field into the Moon. On the limbs the supersonic flow will still imbed the field, but the motion is mostly along the direction of the field lines and therefore the induced electric field is reduced.

The curves of Fig. 1 can be reinterpreted for the case of the inhomogeneous Moon with a low conductivity outer layer. The relation of total current to the k factor shown in the figure applies to the inhomogeneous case because the pressure balance is determined primarily by the total current crossing the lunar equator. Similarly, because the potential drop is determined by the k factor, the total planetary joule loss for a given current is nearly unchanged by the inhomogeneity. When the loss is concentrated in the outer layers, however, the accumulated effect will be diminished because more heat will be lost in radiation through the surface, leaving less to be retained

Under the assumptions of our model, the density of field lines in the interior will drop away to the free-stream value at the centre modified appropriately by the kfactor. The approximation of the circuital theorem used to calculate the induction field implies a magnetic field that increases outward to the surface and then falls away as the reciprocal distance. The vector addition of the free stream and perturbation fields leads to a configuration which agrees substantially with that of Gold regarding the upwind enhancement and shock and a downwind null or quasi-null, provided the mantle conductivity is sufficient. The simplest source for large o is a high temperature—that is, T is about 1,500°-2,000° K.

The conclusions can be applied to any planet. For the Earth $k \sim 1$ and little, if any, field enters the magnetosphere. Unipolar currents would be sheetlike and confined to the surface of the magnetopause. Planets substantially free of dynamo fields but containing an insulating mantle could not support an interior unipolar mechanism, nor could Mars or Venus if the atmosphere insulates. In these cases a degenerate unipolar generator might be imagined where the current closes in the ionosphere and returns to the solar wind12 but does not engage the solid body of the planet. Any unipolar system closing through the planet must be bounded in value by the highest series circuit impedance, here the lower atmosphere.

Finally, plasma must contact the lunar surface in order to drive the unipolar generator. The efficiency is given by the factor (1-k). When $k\rightarrow 1$, all plasma and field are swept to the limbs. This condition, however, is a reductio ad absurdum because it depends on a strong perturbation field. The condition $k\equiv 1$ can therefore never exist and some plasma and field must be decoupled at the surface. The details are complicated by the form of the sheath, and our model does not explore this. For the Moon more detailed calculations to be reported later will be used to refine our expression for the degree of saturation of the unipolar system and the limits on the formation of a shock wave and wake. Future experimental measurements can be employed by an inversion of our deductions to determine the mean mantle conductivity and thus shed light on the thermal profile.

We thank G. Brown, K. Schwartz and E. Putzer of American Nucleonics Corp. for assistance in the computations of the potential field. This paper was presented at the forty-eighth annual meeting of the American Geophysical Union, April 1967, Washington, DC.

The properties of sex pili determined by different plasmids of the Enterobacteriaceae suggest that there may be only two major classes of sex factor, typified by F and the factor of colicin factor lb.

THE study of conjugation promoted by F and other sex factors of the Enterobacteriaceae has been stimulated by the identification on F+ and Hfr bacteria of specialized filaments to which F-specific phages adsorb¹-4. filaments, which are examples of the appendages named "fimbriae" (refs. 5, 6) or "pili" (ref. 7), may indeed be the organs of conjugation^{3,4}. Many other transmissible plasmids have since been shown to determine the synthesis

of pili (refs. 8-12 and an unpublished work) and, to distinguish these pili as a class, we have suggested11 that they, together with the F pilus, should be called "sex pili" as opposed to the various types of "common pili" found on many enterobacteria4-7.

The synthesis of sex pili is determined by the bacterial sex factor, and so the pili can be used to classify the sex factors of plasmids such as R factors or col factors. By this means, it has already been shown that the fi⁺ class of R factors (which repress the function of F in F+R+ cultures¹³) has a sex factor related to F, because F- cells carrying an fi⁺ factor are sensitive to phages that adsorb specifically to F pili^{8,9,14}; whereas the presence of an fi-R factor (one not inhibiting F in an F+R+ strain) does not render cultures susceptible to F phages¹⁴. In many cases^{12a}, however, they are attacked by a newly isolated filamentous phage which attacks cells carrying the pilus¹¹ determined by colI. The sex pili determined by wild-type conjugation factors, other than F and colV (ref. 15), are formed for only a few generations after the factor enters a new host^{11,16,17} and thereafter only 0·01-1 per cent of bacteria are piliated at any one time. The morphology of sex pili must therefore be studied either in a host newly infected with wild-type factors before repression occurs (a "high frequency transfer" or HFT preparation¹⁷) or with mutant factors which do not become repressed¹⁰.

In this article, we describe the morphology of the sex pili determined by eleven conjugation factors, and their interaction with antibody and donor-specific phages as seen in the electron microscope. It can be said at once that all the sex pili thus observed resemble either F pili or the I pili of collb-P9. In addition, sixty transmissible plasmids have been examined by the susceptibility of their hosts to F and I phages, and most were found to confer sensitivity to one or other, but not both, phages.

Morphology of Sex Pili

Cultures of Escherichia coli or Salmonella typhimurium were examined by electron microscopy after negative staining with uranyl acetate. Their plasmids fell into two groups: the first, related to F, included F itself (both autonomous in an F+ strain, or as F'13 (ref. 18) or F-lac (ref. 19); and integrated in the strains HfrH and HfrC), colV-K94 (ref. 15) F₀-lac (ref. 20) and the fi+ R factors, R1 (both wild type and depressed), R100-1 (a de-repressed mutant of R100; refs. 12b and 21) and HFT cultures of R124 and R237 (ref. 8). The second group was related to colI and included de-repressed mutants of the fi- factors, R64 and R144 (ref. 10), as well as HFT cultures of colIb (ref. 11) and colEIa-16 (ref. 12a).

Table 1. CHARACTERISTICS OF SEX AND COMMON PILI

			Clusters				
Pili	Maximum	Axial		of pili	Phage adsorption		
	length (μ)	"canal"	knobs	occur	F	I	
F-like	20.0	Often seen	+	+	+		
I-like	2.0	Rarely seen	+	+		+	
Common	1.5	Prominent	****		-		
(type I)							

The sex pili of members of the first, F-like, group, whether determined by F, $col\ V$ or F₀-lac, or by R1, R100–1, R124 or R237, could not be distinguished from one another by appearance. Those of the second, I-like, group, comprising collb-P9, colEIa-16, R64 and R144, were also indistinguishable from one another, except for the occasional presence of unusually thin filaments associated with collb (ref. 11). There were, however, certain definite differences between the sex pili of the two groups, as shown in Table 1, despite the fact that the appearances varied so much that it was impossible to decide by morphological criteria alone to which group a particular sample belonged. Although I-like pili were usually shorter than F-like pili, their length was in part dependent on the bacterial strain used as host. Thus the pili formed by de-repressed R144 were longer in strain M396 than in strain M385, although both strains are Salmonella typhimurium. The knobs found on the ends of sex pili often have a distinct substructure, and those of F-like pili tended to be larger and more complex than those of I-like pili, which were usually small and undifferentiated. There were usually between one and ten sex pili to a cell,

but occasionally between fifty and a hundred were seen (Fig. 1). In some cultures, sex pili were not randomly distributed on the cell, but tended to arise in clusters from one or a small number of points¹¹.

Host Range of I and F Phages

The first of the two groups of phages used comprised two F phages, MS2 (ref. 22), an isometric RNA phage attaching along the length of the F pilus, and M13 (ref. 23), a filamentous DNA phage attaching to the tip of the pilus. The second group of phages consisted of two isolates of a filamentous phage with a new host range^{12a}. Both were isolated from sewage by enrichment on Salmonella typhimurium carrying a de-repressed ft-R factor, followed by plating on Escherichia coli K12 carrying the same factor, so that unwanted salmonella phages propagated during enrichment could be disregarded. The two isolates may well be the same phage, for their antisera cross-neutralize and neither is affected by high titre antiserum to the filamentous F phage, M13. This new phage we provisionally name an "I phage" to conform with "I pilus", the prototype of the second morphological class of sex pili.

The I phage lysed strains carrying de-repressed mutants of the fi-R factors, R64, R342, R144 and R163, but did not attack those with F, colV or de-repressed mutants of the fi+ factors, R1, R192 or R100-1; thus, its host range evidently comprised strains forming I-like sex pili. It was then tested for its ability to replicate in strains carrying a variety of wild-type plasmids isolated, so far as is known, from independent natural sources. They included colB and Hly, the haemolysin factor of E. coli, which are related to F (refs. 24-27), and colEIa (ref. 28), which is fi-and determines an I-like pilus^{12a}. Results are shown in Table 2, which includes tests on de-repressed mutants¹⁰ and those previously reported^{12b,14} using the F phage, MS2. Of the sixty strains, forty-seven fell into the first two groups.

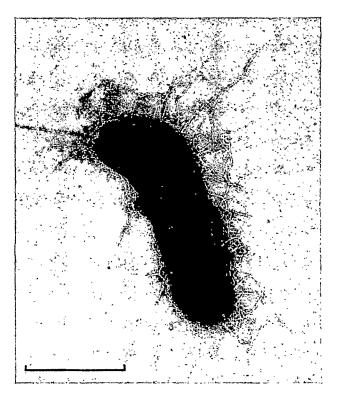

Fig. 1. A cell with an exceptionally large number of I-like sex pili from a culture of *Escherichia coli* K12 carrying a de-repressed mutant of the fi^- factor, R64. Calibration bar, $1\cdot 0\mu$.

The first, which propagated F but not I phage, contained most of the fi+ R factors, no fi- factors and plasmids like F_n -lac and colB. In contrast, the second group which propagated I but not F phage, contained only one strain with an ft^+ factor, twenty with ft^- factors and six carrying plasmids like colI and colEIa. The third group, containing five strains, propagated both phages. These strains and the single fi+ strain of the last group we suspect to carry two plasmids, one F-like, the other I-like. Such strains can easily be prepared in the laboratory; and the factors have already been separated in two of these five strains. The fourth class contained eight strains in which no replication of either F or I phage was detected, and these may contain a third kind of factor. This form of test, however, can give false negative results because the phage did not invariably increase in cultures of wild-type R64 unless HFT preparations were used. It was impossible to obtain HFT cultures with the six cultures which gave negative results, and independent experiments showed that the proportion of cells capable of donation was usually small $(10^{-4} - 10^{-5})$.

Phage Adsorption

The mode of adsorption of F and I phages was examined by electron microscopy, using broth cultures fixed by addition of about 1 per cent (v/v) formalin. Filamentous phages of each group were almost indistinguishable in appearance from the pili to which they attached, and the junction between them had therefore to be revealed by labelling either pilus or phage. With filamentous F phages, an isometric F phage adsorbing along the pilus could be used2, but because no such phage is available for the I pilus, the pilus or the phage was labelled with specific antibody29.

All the phages attached only to sex pili. The two F phages, MS2 and M13, attached to the sides and tips, respectively, of pili of the F-like group but not to pili formed by the I-like group. The filamentous I phages, on the other hand, attached to the tips of pili of the I-like group but not to F-like pili (Table 3). Furthermore, every strain able to adsorb a given phage could propagate it. F₀-lac differed from the other members of the F-related group, for although it does not confer sensitivity to isometric F phages²⁰, Sanderson (personal communication) has shown that it confers sensitivity to the filamentous F phage, M13; as expected, only M13 was seen to adsorb to the Fo-lac pilus (unpublished work of Sanderson and

-, No antibody seen on pili when serum used at a concentration considerably higher than that giving a + reaction with homologous pili.

Serology

The combination of antibody with sex pili can be studied fairly easily by electron microscopy because the filaments lie free of the bacterial body against the background provided by the specimen grid²⁹. Table 3 gives the reactions observed, and Fig. 2 shows the appearance of R1 pili treated with anti-F serum and of Ib pili with anti- \tilde{R} 144 serum. Antisera were prepared by immunizing rabbits with formolized suspensions of $E.\ coli\ K12$ carrying the various plasmids, while the pili were usually examined with the plasmids in Salmonella to avoid reactions with other bacterial antigens. It is clear from Table 3 that the pattern of positive and negative reactions was that to be expected from the morphological type and phage adsorptions of the sex pili. That is, pili determined by F, col V, Fo-lac and R1 showed cross reactions with each other but not with pili determined by collb or fi-R factors, while the latter showed cross reactions with each other

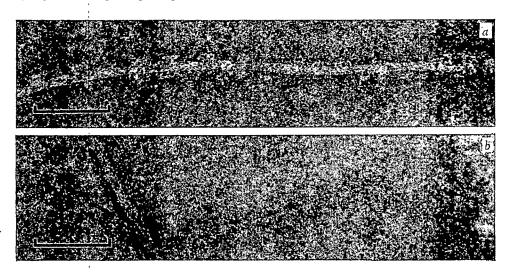

Fig. 2. Sex pill with antibody attached. a, Pilus determined by the f_i^+ factor, R1-16, with anti-F serum. b, I pilus with anti-R144 serum. Note that no antibody is seen on the flagellum. Calibration bars, 0.1μ .

and not with the first group. F_c-lac (ref. 20) and R100-1 (ref. 30) are known from agglutination tests to be antigenically related to F.

Cross reactions with unabsorbed sera demonstrated a relationship within each of the two groups, but to determine the degree of identity cross absorption tests were required. Table 3 shows that anti-F serum combined with R1 pili as well as with F pili. The two types of pili were nevertheless not identical antigenically, for absorption of anti-F serum by bacteria carrying de-repressed R1 considerably diminished the reaction with R1 pili without affecting that with F. In the reciprocal test, where anti-R1 serum was adsorbed with F+ bacteria, the reactions with both R and F pili seemed to be equally diminished. Thus it appears that there is an antigen common to both types of pilus, but that F pili have an extra antigenic component, not represented in R1.

Conclusions

Our principal conclusion is that most sex pili fall into two groups, typified by F and I pili, respectively, whether they are classified by morphology, phage adsorption or antigenic structure. This is so, although the pili are determined by a variety of different plasmids. Thus the same class of sex factor appears to be present in F-lac and in fi+ R factors, although the former is detected by ability to ferment lactose and the latter by drug resistance. The implication is that, although plasmids may manifest themselves in different ways according to the functions they determine and by whether or not their conjugation function is repressed, their sex factors are generally related to F or to the sex factor of colicin factor Ib.

Many plasmids, like colEI-30 (ref. 31), the salmonellin factor³², P-lac of Proteus³³ and the conjugation factor of Serratia³⁴ have still to be examined, as have those of the unrelated genera, Vibrio³⁵ and Pseudomonas³⁶. particularly important that more fi-R factors be tested, because these are defined solely by the negative criterion of a failure to repress F. When classified by other criteria, this group may prove to contain a number of unrelated sex factors with only this negative characteristic in common. Table 2 summarizes the tests so far made on sixty transmissible plasmids of various kinds which show that at least fifty-two are related to F or to the sex factor of collb. The pili determined by two related factors like F and R1 show slight differences in antigenic structure, but long-established clones of a given factor may well come to vary slightly with the passage of time, and relatively minor differences of this kind do not nullify an otherwise

strong taxonomic relationship. Even if further sex factors come to be identified in Enterobacteriaceae, it seems probable that F and the factor of collb-P9 will still be seen to predominate within the group.

The material from which the first I phage was isolated was kindly provided by Dr H. Williams Smith. One of us (N. D.) is the recipient of a grant from the Medical Research Council.

Lethal Unbalanced Growth in Bacteria

by G. W. BAZILL MRC Radiobiological Research Unit, Harwell, Didcot, Berks

The lethal effect of unbalanced growth following damage by ionizing radiation or thymidine starvation is attributed to loss of ability to synthesize an outer cell wall that is strong enough for its essential role in cell division.

TREATMENTS which stop DNA replication but not RNA and protein synthesis—such as ultraviolet or X-irradiation or thymine starvation—often lead to the formation of filamentous cells which can grow by elongation but cannot divide. Filaments can also be induced by some agents which do not directly affect DNA synthesis—for example, penicillin1, crystal violet2, D-amino-acids3 or

magnesium deficiency4. I describe here a hypothesis which ascribes the cause of death in these conditions to inadequate cell wall synthesis resulting from unbalanced

The cell wall in Bacillus subtilis is seen in electron micrographs to consist of three parts: a relatively thick outer wall, an inner wall and membranous structures

continuous with the inner wall (mesosomes). Ryter and Jacob' have shown that the nuclei are often (possibly always) attached to mesosomes at one point. In addition, mesosomes appear to be attached to the septum.

The outer wall is composed of a polymer of three or four amino-acids, acetyl glucosamine and acetyl muramic acid. It is not an osmotic barrier. The inner wall (cytoplasmic membrane) has a high lipid content, is flexible and is an osmotic barrier. The cytoplasmic membrane alone is too weak to resist the osmotic pressure of the cell contents which is of the order of six atmospheres or more, but it is normally supported by the outer wall, which must therefore be very strong and rigid to withstand the high pressure. B. subtilis is typical of Gram positive bacteria. Gram negative bacteria such as E. coli have a rather different cell wall composition. Nevertheless, an outer wall, a cytoplasmic membrane and mesosomes can be seen^{6,7}.

Wall synthesis occurs in two situations: (a) when the cell elongates and the nuclei segregate and (b) when the septum and cross-wall form. Jacob, Brenner and Cuzin⁸ suggested that wall synthesis is co-ordinated with chromosome replication so that, on completion of a cycle of DNA replication, growth of the wall between the points of attachment of the new pair of chromosomes is triggered, thus segregating the nuclei. In the simplest case, DNA replication takes place at the equator of the cell and is followed about one generation later by division at the equator; so an attractive idea in considering what determines the site of septum formation is that one and the same wall priming site may serve first to extend the wall, segregating the nuclei, and then later to form the septum.

The cycle of division and replication can then be visualized as in Fig. 1. The replicative apparatus of the chromosome occupies a site on the inner wall, which is potentially a "primer region" for wall synthesis. At the end of a cycle or replication, the wall primer site is uncovered and synthesis of both inner and outer walls begins. This results at first in elongation; later, the rate of outer wall synthesis (surface area/sec) fails to keep pace with the rate of inner wall synthesis and the inner wall invaginates. This is the essential first step in septum and crosswall formation. Finally, the cross-wall forms and the cell divides.

The role of the outer wall in creating conditions permitting septum formation can be assessed in *B. subtilis* because it is possible to remove the outer wall completely by digestion with lysozyme. In an osmotically stabilized medium, protoplasts are formed which retain all the properties of normal cells, with two exceptions: in liquid media they cannot divide and they cannot regenerate their outer wall.

These considerations suggest the following about the relation of DNA damage to filament formation.

- (1) Failure of invagination of the inner wall leads to filament formation and is caused by mechanical weakness of the outer wall resulting from inadequate synthesis of the outer cell wall material.
- (2) Inadequate synthesis of the outer cell wall is a consequence of blocked DNA replication. Hypothesis (1) is based on work which has shown that although B. subtilis protoplasts cannot divide in liquid media, they can divide in solid media. Division in moderately soft agar was inefficient; the DNA and cytoplasm were shared very erratically between the daughter "cells" and mesosomes were not visible in the dividing protoplasts. On hard agar or gelatine, however, protoplasts were able to revert to the bacillary form, complete with outer wall and mesosomes.

That hard agar can successfully reverse the inhibition of division caused by loss of the outer wall implies a role for the outer wall which hinges upon the only common property of the outer wall and the agar—their rigi-

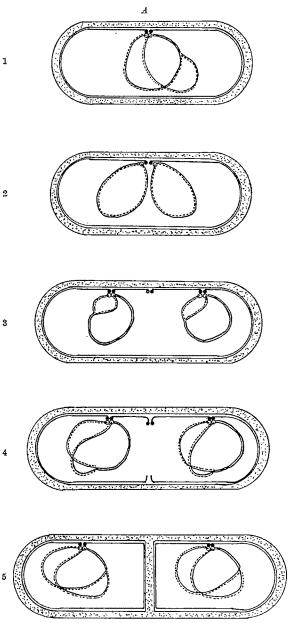

Fig. 1. ○○, DNA polymerase; ●●, wall primer site. For clarity the mesosome is not shown. (1) DNA replication in progress. (2) Replication cycle ended. Wall primer sites ●● exposed. Wall synthesis begins by sequential addition of units at A. The locus of the growth points relative to the cell is a helix of low pitch. (3) Wall continues to grow at A. Elongation of cell and segregation of nuclei. Meanwhile a new round of replication is initiated. (4) Rate of outer wall synthesis fails to keep pace with that of inner wall. Result is infolding of the membrane at A—the first step in septum formation. The mode of growth of the septum is a flat concentric spiral. (5) Septum and cross-wall completed.

dity. This was suggested by Necas^{11,12} and is illustrated clearly in his experiments on yeast protoplasts, which would divide and form colonies when suspended in 15 per cent gelatine but not when placed on it. Similarly, Lederberg and St. Clair¹³ obtained L colonies of E. coli spheroplasts only in submerged culture in solid medium. As discussed by Landman et al.^{9,10}, the stimulus for division of E. subtilis protoplasts seems to be the invagination of the protoplast membrane and it follows from their experiments that invagination is not only necessary but sufficient to trigger septum and cross-wall formation. (No doubt intermediate steps could occur, for example: invagination—produces mesosome—wall primer site—wall extension.)

Invagination of the inner membrane can only occur if the rate of extension of the outer wall (surface area/sec) is less than that of the inner wall. If the outer wall is absent (protoplast) or weak (as in a filament) the inner wall will be permanently distended by the osmotic pressure of the cytoplasm, so that no invagination and thus no division will be possible.

A filament, according to this interpretation, is in a state very similar to that of a protoplast in liquid medium in that it can carry out all the processes of cell metabolism but cannot divide. There is experimental evidence to support this view. Grula and Grula¹⁴ noted that a strain of *Erwinia* formed filaments and spheroplasts simultaneously in some conditions and they concluded that filaments are partial spheroplasts. Chemical analysis of the cell walls of these filaments showed that they contained 30–40 per cent less acetyl glucosamine and muramic acid for each unit of cell mass than normal cells. Further evidence about the failure of filamentous cells to form rigid cell walls has been discussed by Howard Flanders et al.¹⁵.

As presented, hypothesis (1) rests on one interpretation of Landman's protoplast reversion experiments: that the mechanical resistance of the agar or gelatine facilitates membrane invagination and leads eventually to cell division. There is another tenable hypothesis, considered by the same authors: that the hard agar prevents cell wall enzymes and precursors from diffusing away from where they are needed at the exterior surface of the membrane. The model for filament formation described here can readily be translated into these terms (invagination = prevention of diffusion; cell wall weakness = cell wall porosity).

Hypothesis (2) implies a direct relationship between DNA synthesis and outer wall synthesis for which evidence is so far lacking and which requires investigation. There are, a priori, two ways in which DNA synthesis could regulate cell wall synthesis: (a) by controlling the availability of cell wall precursors; and (b) by controlling the availability of wall primer sites.

Regulation of type (a) could be exerted through feedback mechanisms linking the concentration of DNA precursors with the concentration of conjugated uridine and thymidine nucleotides available for wall synthesis. Regulation of type (b) is implied in the scheme for cell division previously outlined (Fig. 1) in which a block in DNA synthesis would prevent the initiation of new sites of cell wall synthesis. Wall synthesis may then either diminish (which will happen if the synthesis occurs in cycles) or remain constant; meanwhile the capacity for RNA and protein synthesis may actually increase as the cell's complement of ribosomes increases to the outer wall and inhibited division.

Weakness or porosity of the outer wall and consequent inhibited division could be caused by any agent (for example penicillin) which selectively inhibits outer wall synthesis. Filaments produced in this way, however, differ from those produced by specific inhibition of DNA synthesis in an important way: the ratio of DNA to cell volume is not changed by selective inhibition of outer wall synthesis. In such filaments the capacity to make a normal cell wall is not lost but merely suppressed, and if the agent is removed division may resume if conditions are favourable. It has been suggested here, on the other hand, that a block in DNA synthesis leads to a reduced capacity for wall synthesis compared with the capacity for other macromolecular synthesis; and removal of the block will not immediately restore this imbalance. It may therefore be useful to distinguish two types of inhibited division: one reversible, in which the ratio of DNA to cell volume is ndar normal and one irreversible, in which the ratio of DNA/cell volume has fallenbelow a critical level.

Some bacterial strains with a particularly strong tendency to form filaments (E. coli B (refs. 1, 17, 18), E. coli B₁₁₁ fil⁺²,

E. coli K12 lon⁻¹⁵) have been studied because they are also unusually sensitive to ultraviolet and X-irradiation. Many of the properties of these strains can be accounted for according to the scheme presented here if it is supposed that the fil⁺ gene is concerned with some aspect of synthesis of the outer wall and that fil⁺ strains even when growing normally make a cell wall the strength and rigidity of which are near the minimum needed for cell division. Being already rather weak walled, such cells would be especially vulnerable to any agent which restricts outer wall synthesis either directly by interfering with the supply or utilization of precursors or indirectly by inhibiting DNA replication. They would pass very easily to the "defective outer wall" state with inhibited division.

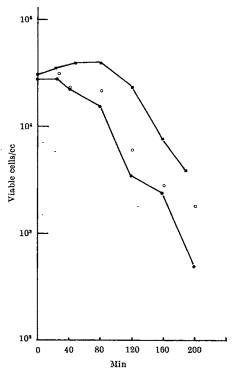

Fig. 2. Comparison of the sensitivity to thymineless death of *E. coli* Bs thy- (fil-, her-, radiation sensitive) and *E. coli* B3r thy- (fil-, her-, radiation resistant). The bacteria were grown in Spizizen minimal medium with 20 µg of thymidine/ml. to a density of 5 × 10⁸ ml., then diluted 10,000 times into minimal medium with no thymidine and plated at intervals on 'Oxoid' nutrient broth with or without 1-2 per cent pantoyl lactone. • • • E. coli Bs thy-; OO, *E. coli* Bs thy, pantoyl lactone plates; • • E. coli B3r thy-.

On this basis, the somewhat paradoxical properties of fil⁺ strains summarized by Kneser¹⁸ can be explained as follows. (a) Filaments are formed which are unable to divide^{1,17,19}. (b) The difference in sensitivity to ultraviolet light between growing and resting bacteria is much more pronounced in fil⁺ than in fil⁻ strains¹⁸. (c) Fil⁺ strains are very sensitive to agents which specifically attack DNA. This sensitivity seems to have nothing to do with the excision repair enzymes, because E. coli B excises thymine dimers as efficiently as E. coli Br (ref. 20). (d) The recovery of fil⁺ strains can be enhanced by a variety of post-irradiation treatments which either slow down growth or speed up excision repair (this process was termed K reactivation by Kneser). Such "rescue" conditions affect only lethal lesions. Neither ultraviolet mutagenesis, phage inactivation, prophage induction nor other macromolecular synthesis is affected. (e) Non-specific treatments can prevent inhibition of division caused by agents which specifically attack DNA^{17,21}. (f) The same genetic locus can control simultaneously radiation sensitivity and filament forming ability^{1,15,22}. (g) The fil gene in E. coli

K12 (where it is termed lon) is involved in polysaccharide synthesis or is closely linked to another gene that is 15,22. (h) Filaments can readily be induced in fil+, radiation sensitive strains by agents affecting not DNA synthesis but cell wall synthesis (penicillin, crystal violet^{1,2}). (i) In some radiation resistant revertants of E. coli B obtained by Witkin, the acquisition of resistance to radiation was accompanied by the acquisition of resistance to penicillin, which causes filament formation in E. coli B1.

It has been suggested (hypothesis (2)) that there is a direct relationship between DNA synthesis and cell wall synthesis; also, that fil+ strains are especially sensitive to inhibition of cell wall synthesis. It follows that fil+ strains should exhibit enhanced sensitivity to anything which blocks DNA synthesis; in particular, they should be more sensitive to ultraviolet irradiation and to thymine starvation than fil-strains. Furthermore, if lethal damage in thymineless death affects the cell wall, not DNA, excision repair enzymes should not play any part and rec+ or rec-strains should be equally sensitive to thymineless death but not to ultraviolet irradiation.

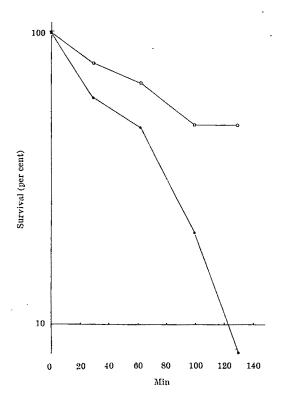

Fig. 3. Protection by pantoyl lactone against thymineless death. After growth in Spizizen minimal medium with 20 μg of thymidine/ml., log phase E. coti Bs thy- were rapidly filtered, washed and transferred at a density of about 10' cells/ml. to: (1) minimal medium without thymidine (••); (2) minimal medium without thymidine but with 1.2 per cent pantoyl lactone (ΟΟ). Suitable dilutions were plated on 'Oxoid' nutrient broth plates supplemented with 10 μg/ml. of thymidine with or without pantoyl lactone (1.2 per cent).

These predictions are in agreement with the results of Cummings and Taylor²³ in their study of the comparative sensitivities of various E. coli mutants to ultraviolet light, mitomycin C and thymine starvation. Also, as expected, E. coli B, thy-(fil+) is more sensitive to thymineless death than the fil-strain B3r thy- (Fig. 2). E. coli B_s thy, however, does not seem to be as sensitive to thymine starvation as the thymineless mutant of E. coli B isolated by Cummings and Taylor.

If the foregoing interpretation of the pattern of thymineless death and ultraviolet sensitivity in fil+ and filstrains is correct, thymine starvation of a fil-strain should reduce its reserve capacity for cell wall synthesis and so induce a state of instability similar to that which has been supposed to be always present in fil+ strains. Thus the model predicts that the curve of ultraviolet dose against survival of a fil-strain irradiated after a period of thymine deprivation should be of the form normally encountered in fil+ strains. This is exactly what was found by Gallant and Suskind²⁴.

Similarly, Fuerst and Stent²⁵ found that thymine starvation sensitized E. coli 15T- to the effects of the decay of phosphorus-32 incorporated in DNA. They inferred from this that thymineless death was a "nuclear inactivation". The suggestion here is rather that damage to the DNA caused by phosphorus-32 tipped the scales toward lethal unbalanced growth and cell wall weakness when the bacteria had already been sensitized (that is partly unbalanced) by previous thymine starvation.

X-ray and ultraviolet damage to fil+ strains can be reduced by plating with pantoyl lactone 18,28. If the relation between the effects of thymine deficiency and ultraviolet damage is as has been suggested, it might be thought that cells suffering thymineless death should also be protected by pantoyl lactone. When added to the culture medium, pantoyl lactone can protect against thymineless death (Fig. 3). When added only to the plating medium, however, there is less protection (Fig. 2). This is consistent with the idea that pantoyl lactone added to plating media protects chiefly by preventing the development of a state of imbalance rather than by reversing a pre-existent state.

In this discussion evidence has been put forward to support the notion that for some cell strains defective cell wall synthesis may be a common factor in death by ultraviolet irradiation and thymine starvation. I think that sufficient evidence exists to make it a useful working hypothesis; nevertheless, some complicating factors have been ignored, notably the possible role of prophage induction, and the premature initiation of a cycle of DNA replication after a block has been imposed27-29. To this extent the model, like most models, is oversimplified.

I thank Mrs Y. Retief for her assistance and J. St. L. Philpot for constructive criticism of the manuscript.

Dispersal of Tropical Marine Shore Animals: Coriolis Parameters or Competition?

JOHN C. BRIGGS Department of Zoology, University of South Florida

Contrary to recent supposition, species gradients cannot be relied on to indicate the direction of successful migrations by tropical shore animals or the direction of the principal ocean currents.

In the low latitude regions of both the Atlantic and Pacific Oceans, the North and South Equatorial Currents move the surface waters in a westerly direction. By comparison, the equatorial countercurrents are weakly developed and move only small amounts of water. The question is whether the predominantly westward movement of tropical waters means that a successful dispersal of shelf animals takes place in the same direction. Theoretically, it may seem logical, and this is the assumption made by Professor H. B. Fell in his article¹ relating both present and fossil distributions to Coriolis (major oceanic current) effects.

As support for his assumption, Fell noted that the molluscan genus Voluta and other groups demonstrated speciation gradients in which the number of species gradually diminished around the world in a westward direction. For the purpose of comparison, I shall examine the distribution of the tropical shore fish genus Entomacrodus. Here, there is also a diminution in the number of species in the same direction: the western Pacific has sixteen or seventeen species; the Indian Ocean has six or seven; the eastern Atlantic has two; the western Atlantic has two, and the eastern Pacific has one. Entomacrodus, however, has just been subjected to a careful systematic study². The relationship of the species indicated that the genus originated in the western Pacific but migrated from there eastward across the Pacific to the New World and then eastward across the Atlantic to West Africa.

Is there any other evidence of successful eastward migrations across the Atlantic and Pacific? Studies on the shore fish fauna in general's have shown that the East Pacific Barrier, the extensive deep-water area that lies between Polynesia and America, has been successfully crossed (migration followed by apparent colonization) by about sixty-two species. Circumstantial evidence was given to show that this was entirely an eastward colonization movement. Apparently, species belonging to typical New World genera have been completely unable to colonize in the opposite direction. At least some of the shore invertebrate groups apparently behave in the same way.

The Mid-Atlantic Barrier is the deep-water area separating the western Atlantic tropics from those of the West African coast. Apart from a group of about twenty-four shore fishes which apparently make their way from the Indian Ocean around the Cape of Good Hope and then westward across the Atlantic, the predominant migratory movement seems to be from west to east4. Many of the transatlantic species range broadly along the western Atlantic shelf but have attained only limited purchase in the east. Others that have achieved broad distributions in the east are clearly representatives of American genera. None of the transatlantic species belongs to genera which are typically eastern Atlantic. There are about one hundred and eighteen such species and they comprise about 30 per cent of the shore fish fauna of tropical West Recent works on West African invertebrate groups also show that an appreciable percentage of the species is transatlantic.

It may be concluded, on the basis of strong evidence for the shore fishes and at least some similar indications for the shore invertebrates, that successful migrations across the Atlantic and Pacific Oceans usually take place in an eastward direction opposite to the flow of the North and South Equatorial Currents. How can this apparently anomalous occurrence be explained? It has been observed

that the region of the Indian and West Pacific oceans has served as the evolutionary and distributional centre for the entire marine tropics4. It seems clear that the unusually stable ecosystems and high level of competition provide the proper environment for the evolution of dominant species that can successfully invade the other regions.

From the Indo-West Pacific, dominant species migrate across the open ocean to America, westward around the Cape of Good Hope into the Atlantic, and northward through the Suez Canal into the Mediterranean. Successful reciprocal migrations are, at least, very rare and may be completely lacking. To judge from the general indications of relationship among the four great tropical marine faunas (Indo-West Pacific, eastern Pacific, eastern Atlantic, western Atlantic), this process has been going on for many millions of years. In the shore fishes, for example, virtually all of the tropical families and most of the genera are probably of Indo-West Pacific origin. Some of the dominant species are so successful that they have been able to establish and maintain circumtropical distributions.

The western Atlantic tropics may be considered a secondary centre of evolutionary radiation. Many species produced in this area have proved capable of migrating eastward to colonize the eastern Atlantic region. Species originating in the eastern Atlantic, however, are apparently incapable of successfully invading the western side. Again, the advantage seems to lie with the area that possesses the richer fauna and higher level of competition. Such movements seem to illustrate well a basic zoogeographic concept which received its modern emphasis from Matthew6—that dominant species arise in certain important centres and gradually become dispersed into the peripheral areas.

The existence of gradients in numbers of species (or genera) across the major barriers may mean only that certain areas have offered more opportunity for evolutionary radiation than others. In the tropical Atlantic and Pacific there is certainly not a positive correlation between the direction of the major currents and the successful migration of shore species across the midoceanic barriers. The Indian Ocean is not separated from the western Pacific by a major zoogeographic barrier and the fauna of the East African coast may be considered an attenuation from that of the Indo-Australian Archipelago. For most groups, there is a decreasing species gradient extending from the latter area westward across the Indian Ocean as well as eastward into the island groups of Polynesia.

In conclusion, I wish to observe that in the tropical oceans the degree of biological competition is probably a more important factor in the dispersal of shore animals than the direction of the major currents. As the direction of the species gradient in recent, tropical animal groups does not necessarily indicate the direction of successful migrations or major currents, there is no reason to believe that fossil gradients can be relied on to give us such information for past epochs.

ASTRONOMY

On the Space Distribution of Identified Quasi-stellar Objects and Radiogalaxies

The ratio of identified quasi-stellar radio sources to identified radiogalaxies in the 3CR catalogue is about 1:2. As the identified sources constitute a large fraction of all the extragalactic sources in the catalogue, and redshifts have been obtained for a considerable fraction, it is clear that the complete identification of all such sources could not change this ratio in a very significant way. It follows therefore that, independent of any optical selection effect, the number of quasi-stellar radio sources is approximately comparable with the number of radiogalaxies down to a radio flux of 9 units at 178 Mc/s.

The redshifts of the quasi-stellar radio sources extend up to about 2 where a limiting value seems to exist. The redshifts of the radiogalaxies in question extend only up to about 0.25, however. Of the sixty-five 3CR radiogalaxies for which redshifts are known, only two, 3C 109 and 3C 295, have shifts greater than this. This means that if we accept a cosmological interpretation of all such redshifts, the quasi-stellar radio sources occupy a spatial volume about a thousand times greater than that occupied by the radiogalaxies. The approximate equality of numbers has then to be explained on the basis that the density of radiogalaxies is about a thousand times greater than the density of the quasi-stellar radio sources. It then appears fortuitous that these two large factors should compensate each other. The situation appears particularly odd in view of the similarities that seem to exist between quasistellar objects and the nuclei of Seyfert galaxies (for example, the high-frequency radio properties of NGC 1275 and 3C 279 and the infrared flux in NGC 1068 and 3C $(273B)^{2.3}$ and between quasi-stellar objects and N-type galaxies (ref. 4; also Oke, J. B., private communication).

The cosmological interpretation of the redshifts of quasi-stellar objects is not supported by the form of the redshift-magnitude plot, at optical and at radio frequencies⁵. The redshift-magnitude plot at optical frequencies becomes a scatter diagram when a $(1+z)^3$ correction for redshift effects is applied⁶, whereas at radio frequencies the plot is already a scatter diagram before such a correction⁵. This is consistent with a gravitational rather than a cosmological interpretation of the redshifts, provided that the low frequency radio emission is considered to arise in a more extended region than the optical emission? It is important that these features appear in the identified sources in the 3CR catalogue, so that the optical features can hardly be said to arise from an optical selection effect.

For sources of very small angular size there does appear to be a correlation between radio flux and redshift⁶; this is consistent with what is found at optical wavelengths for if the radio emission arises in very small volumes, the intrinsic redshift corrections should be put in as for optical emission, and they will tend to give a scatter diagram again.

All these considerations suggest the hypothesis that the quasi-stellar objects and the radiogalaxies are members of the same family of phenomena, and that they occupy similar volumes of space. On this hypothesis the total redshift, z, of a quasi-stellar object would be given by

$$1 + z = (1 + z_c)(1 + z_g) \tag{1}$$

where z_c and z_g are shifts due to the expansion of the universe and to local gravitation, respectively. A similar equation applies in principle for the radiogalaxies. There is, however, no evidence to suggest that z_g for radiogalaxies is much different from zero. So z_c for the radiogalaxies in question extends up to about 0.25. In accordance therefore with our hypothesis, z_c for the quasi-stellar objects extends up to about 0.25. Quasi-stellar objects with small redshifts could be at distances comparable with those required by a cosmological interpretation of the total redshift z_c , but quasi-stellar objects of large z must have $z_g \approx z$.

If one were to survey all sources within z_c about 0.25, most sources would be expected to have z_c near the maximum of 0.25, simply because of volume availability. There would be occasional sources however, at comparatively close distances. If for the moment we assume that all the sources are intrinsically similar, the occasional nearby sources would appear anomalously bright. In Fig. 1 we give the plot of visual magnitude against z for 104 quasistellar objects. Evidently 3C 273 is an exceptional case. On our hypothesis this can be understood if 3C 273 is exceptionally close so that $z \approx z_g$ for this object.

Consider now two quasi-stellar objects with the same z_c , that is to say at the same distance but with different z_g . We expect the object with the larger z_g to appear fainter, in part because of the factor $(1+z_g)^{-2}$ and in part because larger z_g implies a more compact structure with less volume available for a central emission cloud. The assumption that all quasi-stellar objects are intrinsically similar is therefore unlikely to be true. It seems likely that quasi-stellar objects of large z_g will be intrinsically fainter than those of small z_g . This leads to the curious situation that quasi-stellar objects of large z_g , that is, large z_g , may well be systematically closer than quasi-stellar objects of small z.

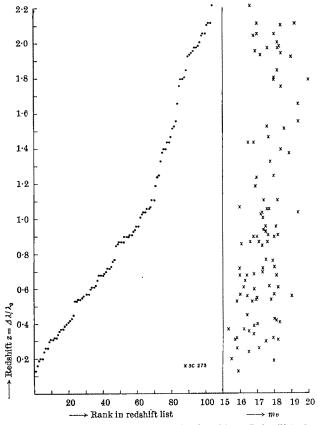

Fig. 1. Distribution of redshifts of quasi-stellar objects. Left: Plot of redshift against rank of quasi-stellar objects in redshift list in order of increasing redshift (1 to 104); right: plot of redshift against apparent V magnitude. Note that 3 $\mathcal O$ 273 at $m_v = 12.8$ belongs to right-hand side of diagram.)

We now arrive at a model in which radiogalaxies and the quasi-stellar objects behave in opposite senses with respect to z. The distances of radiogalaxies increase with z. For the sample for which redshifts are currently available the most distant radiogalaxies so far identified are very frequently N-type and z is about 0.25. The quasi-stellar objects, on the other hand, have distances that decrease with increasing z. The most distant are the ones of small z, while those with z about 2 are comparatively close by. In this picture the greatest distances involved are about 700 Mparsec. The quasi-stellar objects of largest redshift could be at distances of about 50 Mparsec or less. Indeed, the discovery that all the quasi-stellar objects which have absorption lines in their spectra have absorption line redshifts either very close to 1.95 or approximately equal to the emission line redshifts has led to the conclusion that for the objects with z = 1.95 the contribution due to z_c must be exceedingly small, so that a limit to the distances of these objects of about 40 Mparsec is found. Only where a standard spectrum at z = 1.95 is clearly visible can we be sure that this limit is present, but it may be that all of the quasi-stellar objects with large redshifts are comparatively close by.

This model is consistent with there being fewer quasistellar objects of large z than small z. The volume effects are in the correct sense to agree with the distribution shown in Fig. 1, where the usual relation of z to distance would lead us to expect the opposite behaviour.

What is new in the present model compared with previous concepts of a local theory of quasi-stellar objects is that z instead of being uncorrelated with distance is correlated, but in an opposite sense to what is usual.

What will such a model predict for the sources which have not been identified? It is possible that some quasistellar objects have such large intrinsic redshifts that they are not visible optically at all, but because the low frequency radio sources which they have ejected arise in an extended volume, their emissivity in these frequencies is not cut down. These may be the "empty field" or "optic-ally quiet" quasi-stellar objects. Some of the fainter radio sources in the 4C or Parkes catalogues may be quasi-stellar objects at distances corresponding to values of z_c significantly greater than 0.3. Except in special cases, however, we can only expect to detect such sources if they have modest values of z_g , because for values of z_g about 2 they will be too faint to be seen. Thus objects with $(1+z)\gg 3$ will be exceedingly rare.

PLANETARY SCIENCE

Polonium-210 in Marine Plankton

THE occurrence of polonium-210 and its precursor lead-210 in the natural radiation environment has been studied increasingly during the last decade. Radon emanating

from materials in the Earth's crust introduces lead-210 into the atmosphere and there is then a natural fallout of lead-210 and its daughters. These nuclides are then incorporated into natural samples in the hydrosphere and lithosphere. Papers by Burton and Stewart¹, Patterson and Lockhart² and Peirson et al.³ provide data for lead-210 and polonium-210 in air and in rainwater. Hill4 has discussed in detail the concentrations of polonium-210 and lead-210 in foodstuffs, tobaccos and human tissues from various environments, and additional data have been provided by Hill⁵, Holtzmann⁶, Little and McGandy⁷ and others.

Very little work appears to have been done on polonium-210 or lead-210 in the marine environment. Rama et al.8 reported lead-210 values in seawater samples from the Pacific, and Goldberg⁹ extended these data. Cherry¹⁰ reported unsupported polonium-210 at a level of 17 pc./g of dried material in a single sample of marine zooplankton, and Beasley and Palmer¹¹ studied polonium-210 in a few marine samples from Alaska. The primary purpose of the present work was to establish the general level of polonium-210 in marine plankton samples and to this end we made alpha counting measurements on ninety-eight plankton samples obtained from the seas around the Cape of Good Hope during 1965 and 1966. Full details of the sample localities and further particulars will be available elsewhere12.

The experimental techniques were essentially the same as those used previously in this laboratory10; the total alpha activity of a sealed sample and the thorium-series contribution to this were measured and, by subtraction, the uranium-series activity was obtained. The variation with time of this activity was studied. Seventy-three of the seventy-eight zooplankton samples and all twenty of the phytoplankton samples showed a decrease in uranium-series activity on a time-scale of the order of several months. We were consistently able to interpret this decrease as a result of unsupported 138-day polonium-210, and the amount of unsupported polonium-210 present in the samples at the time of collection was calculated by extrapolation.

The results can be summarized as follows. shows, in histogram form, the unsupported polonium-210 content of the ninety-eight samples measured. A modal value of about 3 pc./g of dry plankton is seen to result. Dividing this by an approximate concentration factor of 15 gives an in vivo (wet plankton) concentration of about 200 pc./kg. The unsupported polonium-210 activity in our plankton samples is thus more than an order of magnitude greater than the total polonium-210 reported

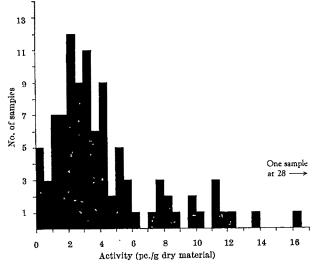

Fig. 1. Frequency distribution of unsupported polonium-210 activity for ninety-eight plankton samples at the time of collection.

in human soft tissues. It is worth noting that the radiation dose to plankton from unsupported polonium-210 at the level quoted will be about 200 mrem/yr. This is to be compared with a total background dose to man from all sources of about 130 mrem/yr. We have, in addition, determined unsupported polonium-210 in four samples of (whole) pelagic fish and find a range of 0.7-3.3 pc./g of dry weight, with a mean of 2.0 pc./g. The wet/dry weight concentration factor is now only 3.3, however, which gives a wet fish tissue concentration of about three times the plankton figure and more than an order of magnitude higher than the values quoted by Beasley and Palmer¹¹ for polonium-210 in salmon, butterfish and whitefish.

The ninety-eight plankton samples showed in addition a time-independent alpha-activity. This activity, which showed a mean value of 2.3 pc./g of dry plankton, is principally due to uranium, radium and daughters (excluding unsupported polonium-210), and, in some cases, thorium-series contributions. The mean value is in general agreement with previous data¹⁰; the contribution of supported polonium-210 to this mean is uncertain but is probably not more than 0.2 pc./g. It thus seems clear that the bulk of the polonium-210 activity, in the marine plankton samples measured, is unsupported by its parent, lead-210, and it follows that the lead-210 to polonium-210 activity ratio must be less than unity in plankton. We are not aware of any published data giving both lead-210 and polonium-210 activities in seawater, but it would be surprising if the lead-210 to polonium-210 activity ratio was not greater than unity in accordance with the general fallout pattern¹⁻³. We conclude that the enrichment factor from seawater to plankton must be larger for polonium-210 than it is for lead-210. Using the values of Rama et al.8 for lead-210 in seawater, namely about 5×10^{-5} pc./g, and combining this with the data given here, we see that an enrichment factor greater than 4,000 results for polonium-210; for lead-210 the enrichment factor must be less than this figure.

The mean unsupported polonium-210 activity in the seventy-eight zooplankton samples was 4.7 pc./g of dry weight, while in the twenty phytoplankton samples it was 2.8 pc./g.

Reference to Fig. 1 shows that eleven samples had values greater than 9 pc./g. It is interesting to note that six of these samples were obtained from localities more than 70 miles away from the coast. As eighty-two of the ninety-eight samples measured were from localities less than 70 miles offshore, it would seem that there is a tendency for offshore samples to contain higher unsupported polonium-210 activity. A possible explanation could lie in the fact that much of the inshore surface water off the west coast of the Cape of Good Hope is upwelled water of Atlantic central water origin¹³. Such water has, in general, less time in contact with the atmosphere than the subtropical surface water found further offshore; because the polonium-210 is presumably derived chiefly from atmospheric fallout a lower polonium-210 content in the inshore waters seems reasonable. An attempt to investigate this correlation in terms of the water masses involved has so far yielded inconclusive results, but it is still worthwhile to draw attention to the possible use of polonium-210 as a natural oceanographic tracer.

Lead and Lead-210 in Rainwater

THERE is a continuing interest in the possible toxicity to man and animals from the present and future concentrations of lead in the environment. The importance of environmental lead was emphasized by Monier-Williams in 1938 (ref. 1), and has since resulted in numerous studies2-4.

Lead exists in the atmosphere as an aerosol which contributes to the body content of lead in man4. Knowing the mean residence time of the lead aerosol in the atmosphere is important, because for any given set of meteorological conditions and a fixed rate of injection, the atmospheric concentration will be an inverse function of the residence time.

Lead-210 has a half-life of 21.4 yr and would be an ideal tracer for stable lead if lead and lead-210 were acted on by the same forces. Because the mean residence time of the lead-210 can be estimated from the ratio of its specific activity to that of one of its decay products, bismuth-210 or polonium-210⁵⁻⁸, this residence time would also apply to stable lead. There are both differences and similarities in the mode of injection of lead and lead-210 into the atmosphere: lead-210 is derived from the decay of radon-222 (a noble gas) which escapes from the soil and is dispersed throughout the atmosphere by winds and convection, while lead aerosols originate from automobile exhaust, in smelter and other industrial operations. The source of both stable lead and lead-210 is at, or very near, the Earth's surface. Except for regional differences in the rates of injection of lead and lead-210 the sites of injection seem very similar, so that both may experience the same meteorological conditions. Both are returned to Earth chiefly by the cleansing action of rainfall from altitudes between 1 and 10 km (ref. 10).

Although fairly extensive measurements of the concentrations of lead-210 in rainwater have been reported5-8, little is known of the concentrations of stable lead11. Furthermore, the concentrations of lead and lead-210 have not been reported from the same samples.

The aim of this study was to evaluate the relationship between lead and lead-210 in the atmosphere. Rainwater was selected because it samples a large volume of air at high altitudes and thereby minimizes effects from local sources. Samples of rainwater were collected on the roof of the physics building at Argonne National Laboratory, and on a farm in Ottawa County, Michigan. The first site is located in a semi-rural area 25 miles west of Chicago and the second is located in an area of farms 125 miles north-east of the Argonne site. This latter site was located 1,200 ft. from the nearest roadway and 15 miles from the nearest city (pop. 25,000). Consecutive samples of rainwater were collected at Argonne from July 1 to September 14, 1966. All samples were collected in porcelain coated steel pans which had been cleaned of dirt and dust immediately before collection of the rainwater. The samples, of between 1 and 6 l., were filtered through a fritted glass filter before analysis. Analyses of both portions of the sample showed that less than 10 per cent of the lead was in the solids retained on the filter. The data in Tables 1 and 2 are for the materials in the soluble portion of the rainwater. The samples were stored in

Patterson, R. L., and Lockhart, L. B., in *The Natural Radiation Environment* (edit. by Adams, J. A. S., and Lowder, W. M.), 383 (University of Chicago Press, 1984).

Table 1. LEAD AND LEAD-210 IN RAINWATER AT ARGONNE NATIONAL LABORATORY DURING THE SUMMER OF 1966

Date	Precipita- tion (mm)	Pb (μg/l.)	²¹⁰ Pb (pc./l.)	Specific activity $(pc./g \times 10^{-4})$
July 1	18-S	10.6	1.08	10.2
July 11	15-8	9.2	0.63	6.8

August 21	51–R	27·5	2·96	10·8

acid-cleaned polyethylene bottles for shipment. Loss of lead to the walls was negligible in these conditions.

Lead analysis and reagent purification were by the standard AOAC spectrophotometric dithizone method¹². Reagent blanks were less than 0.4 µg. Triplicate analyses were performed with each sample containing at least 4 μg of lead. Under these conditions, the standard deviation of a single determination was \pm 5 per cent.

The lead-210 was determined from the beta count rate of its bismuth-210 daughter. These samples were prepared by evaporating the dithizone solution on a 1.5 in. diameter stainless steel planchet, covering it with a 5 mg/cm² aluminium foil and allowing the sample to age for 30 days to attain radioactive equilibrium. The aluminium foil prevented the variable amounts of the alpha emitting activity of polonium-210 which accompanied the lead-210 from being counted. The samples were counted in a foursection, low-background, end-window, gas-flow Geiger counter¹³. Background counting rates were about 0.25 c.p.m. and the counting efficiency for these samples was 50 per cent. Samples of known lead-210 concentrations showed that the procedure gave a chemical yield of 93 ± 5 per cent. Samples were counted for sufficient time to give a statistical counting error (o) of less than 5 per cent.

The concentrations of the stable lead and lead-210 and the amount and type of rainfall in the various samples of rainwater for the Argonne and Michigan sites are summarized in Tables 1 and 2, respectively. The arithmetic mean lead concentration of 18·9 μg/l. at Argonne is essentially identical to the 17.4 $\mu g/l$. in Michigan. Similarly, the mean concentrations of the lead-210 were 1.26 and 1.78 pc./l. at the Argonne and Michigan sites, respectively. These values for lead-210 are a little lower than the average of 2.3 pc./l. found by King et al. and by Glöbel et al. in Germany.

Although the number of data is limited, there seems to be a correlation between the type of rainfall and the concentrations; a shower (rapid, brief rainfall varying in intensity) had lower concentrations than a slow, even rainfall. Thundershowers usually had lower concentrations, but they could also be very high. There does not seem to be a correlation between lead concentration and the length of time between rainfalls. Weather preceding a rainfall, however, may affect the lead concentrations. Thus the September 14 rainfall, with its high values, was preceded by a thermal inversion for the 7 days prior to precipitation. In this case the lead and lead-210 aerosols appear to have been formed at the usual rates, but they were confined to a relatively small atmospheric volume over this long period of time.

The rates of deposition at Argonne are estimated at about 1 µg cm⁻² yr⁻¹ for the lead and 0.08 pc. cm⁻² yr⁻¹ for the lead-210. These estimates are based on this series representing 20 per cent of the measured rainfall at this site during 1966, a mean weighted lead content of 10.6 µg/l. (each result multiplied by its respective depth of rainfall) and mean weighted lead-210 content of 0.83 pc./l. The contribution of these materials to those already present in the soil is therefore small. A brief study near Argonne showed that the soil contained about 20 µg of lead and 1.5 pc. of lead-210 per g of dry material. This lead concentration is similar to Swaine's estimate of 16 $\mu g/g$ world wide¹⁴. The lead-210 concentration is probably also of the same order as the world average. With these values for lead and lead-210 and a soil density of 2 g/cm³, the contribution of both lead and lead-210 to the top 15 cm (6 in.) of soil would be 0.2 per cent per year. This neglects leaching of the lead from the soil or run-off of the rainfall before it can enter the soil.

The specific activities of the lead (pc. 210Pb/g Pb) are also shown in Tables 1 and 2. These values for the two series are much more nearly constant and give an average value of 6.7 and 10.4×10^4 pc./g at the Argonne and Michigan sites, respectively. Student's t test indicates the specific activities to be significantly different (P < 0.01). The correlation coefficients for the concentrations of lead and lead-210 in the two series of data were 0.98 (P < 0.0001) for the Argonne and 0.63 (P < 0.1) for the Michigan samples. The lower level of significance of the latter is probably because of the small number of samples.

These data show that there is good mixing of lead and lead-210 in the atmosphere before they are returned to the Earth in rainfall. Thus lead-210 will be a valid tracer for stable lead in the atmosphere, and it would appear that the meteorological conditions which affect the concentrations of lead and lead-210 do not appear to substantially affect their relative mean residence times in the atmosphere. A similar result was noted by Kuroda¹⁵ in an analysis of fallout from weapons testing, that is, the concentrations of several radioisotopes in rainwater varied over a wide range, but the ratios of their concentrations were very uniform, varying only as a function of decay rates. The mean residence times established from lead-210 daughter assay may also apply to the total lead in these same samples. Burton and Stewart⁵ found a mean residence time of 29 days for lead-210 in the total atmosphere and 22 days for the troposphere. Lehmann and Sittkus reported 33 and 14 days from rain and air samples, respectively. Fry and Mennon⁸ estimated the mean residence time to be about I week. This lower value may be caused by the high frequency of rainfall in the area studied. From these data and from the correlation between lead and lead-210 established in this study, a mean residence time for stable lead of about I month is indicated.

The lack of correlation between lead and lead-210 in air samples from about 1 m above the ground 16 suggests that atmospheric mixing at low altitudes does not eliminate local variations in the rate of injection of one or the other of these materials. Consequently, it appears that the radioactive isotope is an adequate tracer for estimation of the residence time of stable lead only in rainwater or perhaps in air from higher altitudes.

We thank David Masters for technical assistance.

Response of Soil Bacteria to High Temperatures and Diurnal Freezing and Thawing

Previous experiments1,2, both with known organisms and unidentified aerobic organisms isolated as airborne contaminants, indicated that spore forming organisms did not readily grow or survive in vegetative form in freeze-thaw conditions. Severe freeze-thaw conditions are thought to exist on Mars and spore forming organisms are most likely to survive attempts at sterilization, and so we speculated that spores remaining on spacecraft which have been subjected to sterilization procedures would not grow on Mars even if nutrients and water were present. Detailed experimentation with several different strains of Bacillus subtilis variety niger, however, revealed that certain strains could grow, at least marginally, in freezethaw conditions (+25°-70° C) where thaw periods were as short as 5 h, and growth was good when thaw periods were longer. This result was obtained only when a particularly favourable medium, heart infusion broth, was used. Nevertheless, this indicated that spore formers could survive and grow vegetatively in freeze-thaw conditions, if provided with an otherwise sufficiently favourable environment.

In order to further test the ability of potential spacecraft contaminants to survive and grow in freeze-thaw conditions it was decided to work directly with soil samples. Soil was obtained from a flower bed outside the laboratory, air dried and screened to remove bulk materials. Samples (100 mg) in 5 ml. vials were heated at 135° C for various times between 16 and 144 h and at 145° C and 200° C for 24 h. Sterile soil extract or heart infusion broth was then pipetted into the vials which were sealed and incubated at room temperature (25° C). (Soil extract was prepared by autoclaving 1,000 g of soil with 1,000 ml. of water for 30 min and filtering the subsequent suspension. The resulting clear fluid was sterilized by autoclaving for 15 min and used directly in the experiments.) In each case, between twenty-four and fortyeight samples were assayed by microscopic examination and the percentage of vials showing growth of microorganisms was calculated. The results are shown in Table 1.

Table 1. Percentage soil samples having viable organisms after varying time at 135° c. 145° c and 200° c dry heat

Time at 135° C	Percentage samples viab Soil extract	le at room temperat Heart infusion
16 h	100	
24 h	100	100
48 h	100	100
72 h	100	9
96 h		0
120 h		0
144 h		. 0
Time at 145° C		
24 h		26
Time at 200° C		
24 h		n

Some of the 16 h and 24 h vials were also subjected to several cycles of freezing and thawing after heating and were shown to have survivors.

Because contaminating micro-organisms on board a spacecraft would probably be low in total numbers, an experiment was conducted to determine the quantity of soil which, when inoculated into glucose broth, would yield a population of micro-organisms when incubated in freeze-thaw conditions.

A glucose mineral salts medium (0.2 per cent magnesium chloride, 0.5 per cent sodium chloride and I per cent potassium nitrate) buffered at pH 7.0 with phosphate was inoculated with dried screened soil to give 100, 10, 3, 1, 0.3, 0.1, 0.03 and 0.01 mg/ml. The suspension was stirred vigorously and distributed in each case in 2 ml. quantities to each of twenty-five 10 mm tubes, which were plugged with cotton. A baseline plating on glucose agar was made, and the tubes frozen at -75° C. They were then cycled daily between +25° C and -75° C with 4-1.5 h allowed at $+25^{\circ}$ C. The results are shown in Table 2.

Table 2. RESULTS OF SOIL EXPERIMENT USING VARIOUS AMOUNTS OF UNSTERILE SOIL

Amount of soil (mg/ml.)	Colony counts (ml. initial)*	Colony counts (ml. after 11 cycles of freeze-thaw)
100	1.0×10^{8}	1·4×10°
10	1.0×10^{5}	3.4×10^{7}
	3.0×10^{4}	1.7×10^{8}
3	1.0×10^{4}	4.7×10^{8}
Ō•3	3.0×10^{3}	7.3×10^{7}
0.1	1.0×10^{3}	1·8×10 ³
0.03	3.0×10^{2}	7·6 × 10°
0.01	1.0×10^{2}	5.6×10^5

* Assay was made by serial dilutions on highest soil concentration and extrapolations made for lower concentrations.

It is readily apparent that at the lowest concentrations used the available micro-organisms can grow in freezethaw conditions, even after only about 48 h total growth time. No effort was made to determine the nature of the organisms producing the growth in this experiment. It may therefore involve either spore formers or non-spore formers, or both.

To determine the effect of freezing and thawing on micro-organisms which survived heating in soil, 100 mg amounts of dried screened soil were distributed to each of 1,320 10 mm tubes. These were divided into sixty sets of twenty-two tubes each. Twelve sets were subjected to each of five different sterilization periods as follows: 2, 4, 8, 16 and 24 h at 135° C dry heat. Each group of twelve sets was further sub-divided into couples, and the tubes in each couple were incubated with 2 ml. of the following sterile media.

- (1) Difco heart infusion broth
- (2) Mineral salts—glucose
- (3) Mineral salts—fructose
- (4) Mineral salts—maltose
- (5) Mineral salts—lactose
- (6) Mineral salts—glucose+fructose+maltose+lactose

The sugars, when used individually, were at a concentration of 0.2 per cent. When used in the mixture each sugar was at 0.05 per cent, yielding a total concentration of 0.2 per cent.

Media containing sugar, in addition to heart infusion broth, were used in this experiment because we thought that photochemically produced sugars might be available on Mars. These sugars could serve as carbon sources for microbial growth.

Baseline data were obtained after heating by plating on each of the media, supplemented with agar, and counting the resulting colonies. After 2 h heating the population density was reduced to approximately 10⁴ organisms/g of soil. Four hours or more heating reduced this density to less than 103 organisms/g of soil. In no case were baseline populations sufficient to be detectable by microscopic examination. One set (twenty-two tubes) from each couple (two sets) was incubated at room temperature for 8 days and assayed by microscopic examination. In all cases, every tube revealed the presence of significant growth. The other set from each couple was subjected to freeze-thaw using a thaw period of approximately 6 h. After 25 days of such cycling, half of the tubes from each set were assayed by microscopic examination, or by making serial dilutions and plating in duplicate on the same medium as was used for the original incubation, but with the addition of 2 per cent agar. Positive growth was recorded for any tube in which the organisms were microscopically apparent or in which ten or more colonies developed from plates prepared from second dilution tubes, after at least 7 days' incubation. Dilutions were in steps of 1:10. The results are shown in Table 3.

Table 3. No. of soil samples showing growth during freeze-thaw cycling after various times at 135° c $\,$

No. of		Trank				
hours at 135° C	Fructose	Lactose	Maltese	Glucose	Mixture	Heart infusion
2	10†	11	11	11	11	10†
4	8	11	11	6†	10	11
8	1	1	3	6	2	9†
16	0	1	1	2	0	6
24	0	7	0	1†	0	1†

Eleven samples for each treatment except those marked † which had ten.

As noted here, all the tubes have micro-organisms capable of growth even after 24 h of heating when incubation is at room temperature. In contrast, the introduction of freeze-thaw conditions greatly reduces this capability in tubes heated for 8 h or longer. In some tubes of each medium organisms are unable to grow even after 4 h of heating when incubated in a freeze-thaw environment. After 24 h the organisms in nearly all the tubes are unable to grow in the freeze-thaw environment in all media except lactose. In this case a definite anomaly exists, which, while it has not yet been explained, is probably an artefact. The result is apparently very much dependent on the medium used, heart infusion broth sustaining superior growth. In heart infusion, a population of microorganisms grows up readily in nearly all tubes heated for 8 h and then subjected to freeze-thaw. Even here, however, only one of the ten tubes tested which had been heated for 24 h revealed the presence of detectable micro-This appears to indicate that freeze-thaw organisms. conditions, following heat treatment, impede the growth of organisms placed in an environment where they would otherwise grow.

It should be noted that all growth experiments were done in conditions of ample water, a situation not likely to be encountered on Mars. The likelihood of the contamination of spacecraft by even small samples of dirt may also be questioned. It seems clear that the survival of bacteria in even small amounts of heat treated soil is striking and the inclusion of such dirt must be rigorously guarded against in planetary exploration in order to exclude contamination of experiments designed to analyse planetary surfaces for evidence of life and life related compounds. The conditions required for growth on the planetary surface, however, are unlikely to be met on Mars and explosive bacterial growth is not to be expected according to prevailing notions of the Martian environment.

Mantle Convection and Sea-floor Spreading in the South-west Pacific

THE interpretation of south-west Pacific structure recently proposed by Summerhayes1 is, in many respects, in agreement with suggestions previously made by myself2. Both emphasize the importance of sub-crustal convection and sea-floor spreading in determining the structure of the region, and both recognize the development of island arc structures to the north and south of New Zealand.

On one significant issue, however, the nature of the Antipodes Fracture Zone, east of New Zealand (Fig. 1), there is a basic difference of opinion which has wide implications in the elucidation of the regional structure and the mechanism of mantle convection and sea-floor spreading. While the original description of the Antipodes Fracture³ presented evidence for transcurrent displacements and suggested comparison with the parallel Alpine Fault⁴ of New Zealand, Summerhayes¹ regards the Antipodes Fracture as a rift margin fracture produced by movement of the crust away from the crest of the East Pacific Rise.

Summerhayes's hypothesis suffers from oversimpli-It is concerned primarily with the role of sub-crustal convection currents emanating from the East Pacific Rise, and fails to take fully into account the effects of similar currents rising beneath the Indian-Antarctic and Pacific-Antarctic ridges, south-west and south of New Zealand. This oceanic ridge system forms a broad are, concave northward, within which northmigrating convection currents tend to converge. resultant movement of crustal blocks expected from such a convective system would be in a general northward direction, and I (ref. 2) envisage a mobile belt extending from the region south of New Zealand to Fiji and Samoa, within which essentially northward migration of the crust has been helped by a series of parallel N.E.-S.W. fracture zones.

The distance separating the Antipodes Fracture Zone from the crest of the East Pacific Rise increases northeastward from about 1,750 km to 2,500 km, a divergence

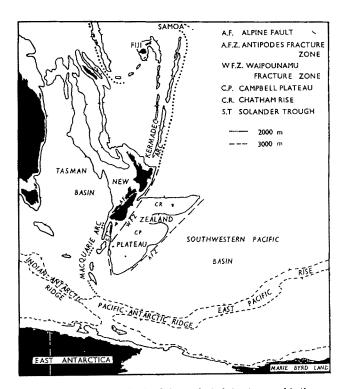

Fig. 1. Sketch map showing localities, geological structures and bathymetric features mentioned in the text.

of 20°-25° of arc. Summerhayes's hypothesis of the rifting apart of these two features requires therefore a rotational movement of the New Zealand Plateau over distances up to 2,500 km in a north-westward direction. Movement of this magnitude and trend cannot be accommodated by the Alpine Fault; neither is there evidence of displacement or foreshortening on a comparable scale of the perpendicularly aligned Mesozoic ridge and basin structures north-west of New Zealand. A logical corollary of the hypothesis—concurrent rotation of northern New Zealand and the structurally continuous regions further north-involves movements too excessive to be seriously considered.

Menard⁵ notes significant differences in the morphologies of the East Pacific Rise and the Pacific-Antarctic Ridge, comparing the latter with the Mid-Atlantic and Mid-Indian ridges, which are commonly accepted as being of rift origin. Thus there is evidence of rifting between the southern end of the New Zealand Plateau and the Pacific-Antarctic Ridge, complementary to the northward movement of the Plateau. No such morphological evidence supports the hypothesis of rifting associated with the East Pacific Rise. The morphological differences also indicate that, contrary to Summerhayes's1 suggestion, the supposed south-westward axial spread of the East Pacific Rise stopped well short of the Macquarie Arc. and could have had little direct influence on its evolution.

The E.-W. strike of both Tertiary and pre-Tertiary formations on the Campbell Plateau¹ and Chatham Rise^{3,6,7} confirms the existence of crustal stresses compatible with northward movement, but is difficult to reconcile with north-westward migration. The E.-W. dilatational rifting of the Solander Trough and Waiau Depression¹, south of New Zealand, would have been opposed by crustal movements having a westward component, although not at variance with the local E.-W. tension implicit in northward movement of the New Zealand Plateau.

Summerhayes's1 designation of the Alpine Fault as a transform displacement separating oppositely directed island ares is again misleading. The Alpine Fault has a complex history, dating back at least to mid-Mesozoic times—long before the inception of the Tertiary island arcs north and south of New Zealand. Moreover, the extension of the Alpine Fault north of Cook Strait is questionable, and the Kermadec Arc is associated, not with the Alpine Fault, but with the Waipounamu Fracture³ east of New Zealand.

Summerhayes1 cites the existence of parallel linear magnetic anomalies in the Southwestern Pacific Basin as evidence of rifting apart of sialic blocks on either side of the East Pacific Rise. In view of the geological evidence against rifting in this region and the present incomplete state of knowledge of the geomagnetic circumstances of the south-west Pacific, such an inference is not permissible.

The former close proximity of New Zealand and Antarctica has long been contemplated because of the occurrence of similar rocks-greywackes, schists and granites—on the Chatham Rise^{6,7} and Campbell Plateau⁸ and in Marie Byrd Land9. The separation, however, of New Zealand from Antarctica cannot be explained by simple rifting away from the East Pacific Rise as Summerhayes suggests. Even if allowance is made for rotation of the New Zealand Plateau, the discordance between the E.-W. regional strike of the Chatham Rise and Campbell Plateau and the N.W. to N.N.E. strike of formations in Marie Byrd Lando is excessive. Furthermore, the intensity of folding in West Antarctica is considerably greater than on the Campbell Plateau and Chatham Rise.

The opening of the Australian-Antarctic and Atlantic-Indian-Antarctic basins, following the disruption of Gondwanaland, implies eastward migration of Antarctica with respect to the present position of New Zealand.

Reassembly of the fragments of Gondwanaland suggests that western West Antarctica originally lay close to the south or south-west of New Zealand 10, and nowhere in the vicinity of the developing East Pacific Rise. Separation of New Zealand and Antarctica is here attributed to rifting apart along the Pacific-Antarctic and Indian-Antarctic ridges, followed by simultaneous relative northward movement of the New Zealand Plateau and south-east migration of Antarctica. The virtual absence of Tertiary sediments in Antarctica¹¹ contrasts with their wide occurrence on the Chatham Rise6,7 and Campbell Plateaus, and may indicate that separation began in late Mesozoic or early Tertiary times. This hypothesis does not deny emanation of sub-crustal convection currents from the East Pacific Rise; it recognizes them as competitors with the N.E.-directed currents in maintaining northward migration of the New Zealand Plateau.

Palaeocene Core from the Norwegian Basin

DURING the second cruise of the Atlantic Seal, the Texas Instruments, Inc., contract oceanographic research vessel, a Palaeocene core was taken from the Norwegian basin at 66° 21' N. and 00° 18' E. (Fig. 1). The collection and analysis of the core were part of the US Naval Oceanographic Office, Marine Geophysical Survey Project. The occurrence of this core is important for several reasons: it provides knowledge of the diversity of Palaeocene planktonic organisms in a high latitude; and it establishes the existence of a seaway in this part of the North Atlantic in Palaeocene times.

The core (AS 1-9) is 332 cm long and was recovered from a gentle slope in 3,017 m of water. It consists of two distinct lithological units (Fig. 2) separated by a disconformity. The top 60 cm accumulated during Late Pleistocene and Recent times while the underlying 272 cm represents deposition during the Palaeocene.

The upper unit contains three poorly defined layers of soupy sediments which are, from top to bottom, sandy mud, mud and sandy silt. They are the products of sedimentation in deep marine waters.

A disconformity marks the boundary between younger sediments and the Palaeocene beds below. The Palaeocene sediments are clay, mud and sandy mud and are dark greenish grey and dark brown in colour. They consist of partially indurated (Fig. 2) volcanic lutites, very poorly sorted, strongly coarse-skewed and mesokurtic to very platykurtic. All sand and silt-sized materials are angular scoria fragments and appear to be the products of submarine erosion of basaltic scoria. Although it is impossible to locate the source of this material from the analysis of a single core, it is suggested that basaltic extrusives of the Brito-Arctic province1 at one time

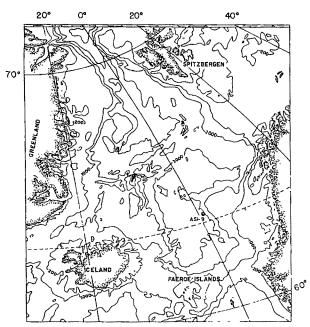

Fig. 1. Bathymetric map of the Norwegian basin showing the location of Palaeocene core AS 1-9.

cropped out nearby. The parent rock has broken down to predominantly clay-sized material and subordinate amounts of silt and sand during submarine weathering and transportation. This combination of size grades produces the strongly coarse-skewed character of the size distributions.

In addition to sediment analysis, palaeomagnetic measurements were also made on this core and interpreted by Dr Opdyke of this observatory. These show a normally magnetized section from 100 to 216 cm overlying a reversely magnetized section from 216 to 316 cm. Seismic profile records taken in conjunction with this core site show a gently sloping bottom topography. Beyond this, the resolution is generally poor but some discontinuous, horizontal layering is discernible.

Foraminifera in the top 60 cm of the core are predominantly planktonic and represent a typical modern subarctic assemblage², characteristic of the latitude at which the core was taken. Globigerina pachyderma (Ehrenberg) and Globigerina bulloides d'Orbigny are the most dominant, while Globigerina quinqueloba Natland is common and Globorotalia scitula (Brady) and Globorotalia inflata (d'Orbigny) are rarely present. The overall aspect of the fauna suggests a late Pleistocene-Recent age.

Benthonic foraminifers, constituting as much as 10 per cent of the total population, are largely calcareous. Common species include *Planulina wuellerstorfi* (Schwager), *Pyrgolaevis* Defrance, *Cassidulina translucens* Cushman and Hughes and *Cassidulina norcrossi* Cushman. The predominance of planktonic species and the presence of bathyal type benthonic species and the presence of bathyal type benthonic species such as *Planulina wuellerstorfi* suggest that a water depth similar to that of the present prevailed around the core site during the deposition of the top 60 cm of the core.

As described earlier, the layer between 60 cm and 100 em is similar in lithology to the layer below. Except for a few Pleistocene-Recent species, typical Palaeocene calcareous foraminifers are absent in this interval, although a few arenaceous species such as Bathysiphon nodosariaformis and Rhabdammina cylindrica which are diagnostic of the layer below occur. The layer below 100 cm is characterized by common occurrences of Palaeocene foraminifers (Table 1). A lower Landenian (lower Upper Palaeocene) age for this layer is established on the basis of four planktonic species. Globigerina triloculinoides, the most abundant planktonic species in the Palaeocene section of the core, is known from sediments ranging in age from Danian (earliest Palaeocene) to early Landenian (late Palaeocene), at which time Globigerina triangularis evolutionarily branches off from G. triloculinoides³. Globorotalia varianta is reported from Danian to lower Eccene of Europe and northern Africa⁴ and from Dano-Montian (lower Palaeocene) to lower Upper Landenian in the US Gulf Coast⁵. Globorotalia imitata is recorded from Dano-Montian to lower Upper Landenian5.

The benthonic species, which represent nearly half of the total population, further support a Palaeocene age for the fauna. Ceratobulimina perplexa, Pullenia quinqueloba angusta, Pulsiphonina prima, Anomalinoides midwayensis and Pseudoparella madrugaensis are all characteristic of the US Gulf Coast Palaeocene. Glomospira iranensis, originally described from the Palaeocene of Iran, was reported to be extremely rare in the Danian but common in Palaeocene sediments about 15 feet above the top of the Danian.

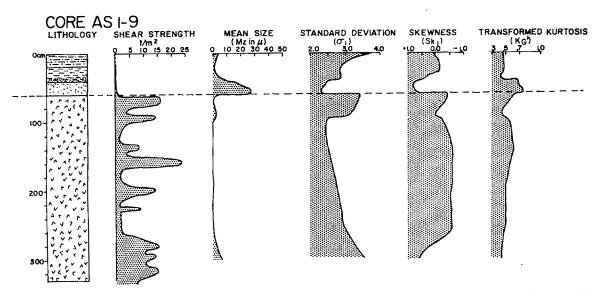

Fig. 2. Lithology, shear strength and grain-size measures of core AS 1-9. Pleistocene-Tertiary boundary is indicated by a dashed line. Note abrupt increase in shear strength below the boundary which reflects change from unconsolidated Pleistocene sediments to partially indurated, Tertiary volcanic lutites.

The affinities of the Palaeocene fauna in AS 1-9 seem to be with the circum-Atlantic and Tethys region such as the US Atlantic Coast⁷, the Gulf Coast and Caribbean region⁸, northern Sinai⁹, Belgium¹⁰ and the northern Alps¹¹. There are particular affinities with the Swedish Palaeocene¹². The present fauna, however, is distinct in that it has a larger variety of species of the family Pleurostomellidae and Nodosariidae and lacks species of Nonion, Elphidiella, and Astegerina. Differences in faunal composition between these two areas may be due to a shallower water environment for the Swedish Palaeocene, as modern representatives of species related to this Palaeocene assemblage seem to support a shelf depth for the Swedish Palaeocene and an upper bathyal depth for AS 1-9. The upper bathyal depth establishes the presence of a seaway in the Norwegian basin during the

Sediment samples studied from different levels in the Palaeocene section of the core seem to contain essentially the same fauna. It is noteworthy, however, that in the normally magnetized Palaeocene section of the core (100-210 cm), species of Globorotalia are absent. As both G. varianta and G. imitata range higher up in the Palaeocene section elsewhere, the absence of Globorotalia in this upper section of the core may be attributed to some changes in the local environment.

In lower latitudes the Landenian is the time when an explosive evolution of marine planktonic biota took place following the drastic decline of marine planktonic life at the end of the Cretaceous¹³. The upper half of the Palaeocene section in lower latitudes is generally characterized by diversified species of Globorotalia, many of which possess a distinct peripheral keel. The impoverished planktonic foraminiferal population in the Norwegian Sea near 66° 30' N. and the lack of any keeled Globorotalia suggest that climatic zones existed in middle Palaeocene seas.

To our knowledge this is the most northerly Palaeocene deep sea sediment recovered from the North Atlantic. Further coring in this area is indicated and should help resolve such problems as faunal diversity in high latitudes, palaeo-oceanography and the various geological and geophysical problems related to ocean floor spreading and continental drift.

We thank W. A. Berggren of Woods Hole Oceanographic Institution for helpful discussions on Palaeocene foraminiferal faunas. This work was supported by Texas Instruments Inc. and by the US National Science Foundation.

Palaeomagnetic Result from the Hook Intrusives of Zambia

THE Hook batholith is a composite granite mass intruding meta-sediments of the Katanga system in Zambia and situated at about 15° S., 26.5° E. The chief part of the batholith is syntectonic, but associated with it are numerous post-tectonic satellite bodies of diorite, syenite and gabbro¹. An age of $500 \pm 17 \times 10^6$ yr has been reported by Snelling et al.2 using the Rb-Sr method on a specimen of red granite which is also believed to be post-tectonic.

In September 1964, oriented cores were drilled at six sites in the satellite bodies: four in gabbro and one each in syenite and diorite. The natural remanent magnetization of specimens cut from the cores was measured with a spinner magnetometer3, and alternating field demagnetization techniques4 were employed in an attempt to isolate a primary component of magnetization. In only three of the six sites did the initially scattered directions respond to treatment, showing a grouping of directions after treatment in fields between 10 and 20 mwb.m-2: higher fields led to the onset of instability and the directions became more scattered again. The mean directions obtained using the closest grouping at each site are themselves fairly well grouped, and are believed to represent the direction of thermoremanence acquired when the rocks cooled. The site means are shown in Table 1.

Palaeomagnetic poles for the three sites were combined yielding a mean North Pole position as follows: latitude 14° N., longitude 23.5° W., K = 13, $A_{95} = 36$, where K is the precision parameter, and A_{95} the semi-angle of the cone of confidence.

It is unlikely that results from three sites are sufficient to average secular variation, and the result should therefore be treated with some caution. But the mean pole is close to that obtained from a much more detailed study of syenitic rocks in Malawi which are of a similar age3. The Malawi results give those reported here greater

Table 1

Current Density Measurements in Atmospheric Electricity

In 1929, Watson¹ pointed out that very close to the surface of the Earth the atmospheric electric current, in normal fine weather field, is carried only by positive ions, so that the current density can be computed from

$$J = E_s \lambda_{+s} \tag{1}$$

where J is the density of the current from ionosphere to Earth, E_s is the electric field at the surface, and λ_{+s} is the conductivity of the air at the surface due to positive ions. The electric field and the conductivity, however, are measured usually at a height of approximately 1 metre. The density of the current due to conductivity, $J_c(1)$, at this height is

$$J_c(1) = E(1)\{\lambda_+(1) + \lambda_-(1)\}$$
 (2)

where E(1) is the electric field at 1 metre and $\lambda_{+}(1)$ is the conductivity due to positive and negative ions at 1 metre. The diffusion current is usually neglected and it is assumed that the current density is approximately equal to the density of the conduction current at 1 metre, so that it can be computed from equation (2). This assumption is supported by the observations of Nolan^{2,3} and Hogg⁴. It will be shown here that this assumption is not correct and that the current density should be estimated from

$$J = E(1).\lambda_{+}(1) \tag{3}$$

This statement can be proved by three arguments which will be discussed here shortly.

In the first place, the observations of Hogg and Nolan do not justify the use of equation (2) to compute the current density. Measurements show that E_s and E(1) are nearly equal^{1,2}. In quasi-static conditions the current density is independent of height, so that it can only be computed from equation (2), if $\lambda_{+\epsilon} = \lambda_{+}(1) + \lambda_{-}(1)$, that is if the conductivity due to positive ions close to the surface is approximately twice that at a height of 1 metre. Observations of Hogg and Nolan seem to prove this, but, referring to their papers, some objections can be made. Nolan performed his observations at a place which is not representative of most atmospheric electric observatories: "... the station is exposed at a place between two houses, with high ground on a third side...." Objections can also be made to the methods used by Hogg. Observations at various heights were performed in different seasons of the year and the apparatus was changed during the measurements. Although large corrections were applied to make the observations comparable, results obtained in this way cannot be very reliable.

Moreover, the results of Hogg and Nolan are in contradiction with the observations of Watson¹ and O'Donnell5, who observed $\lambda_{+s} \approx 1.15 \lambda_{+}(1)$. We may therefore conclude that the observations of Hogg and Nolan do not prove the validity of equation (2) for estimating the current density.

Second, from theoretical arguments it can be shown that equation (3) is a better approximation of the current density. In 1929 Watson pointed out that space charge, transported by atmospheric turbulence, contributes to the current density. He supposed that I metre above the surface, transport of space charge by eddies cancels the conduction current due to negative ions, so that the current density could be estimated with equation (3). As Watson did not give the cause of this space charge, his ideas were abandoned in favour of the results of Hogg and Nolan. In my opinion, however, Watson's idea was right: negative space charge, in the form of negative ions, is transported downward neutralizing almost completely the conduction current due to negative ions. The explanation is as follows. The conditions for inactivation of ions below the level of 1 metre are about the same as the conditions above this level, if there is some atmospheric turbulence. Above the height of 1 metre the number of ions created is equal to the number of ions that is inactivated, so the net production of ions below 1 metre is equal to the additional ionization close to the surface. It can be shown that the net production below 1 metre is less than 10⁶ pairs m⁻² s⁻¹. When we assume that no negative ions are emitted by the surface, then the net production below 1 metre must be equal to the net flux of negative ions that passes this level. The flux of negative ions that drift upwards under the influence of the atmospheric electric field is of the order of 107 ions m⁻² s⁻¹.

The total net production is much smaller, 10° ions m⁻² s⁻¹, so that negative ions must be transported downward by eddies, almost neutralizing the conduction current due to these ions. The approximations are not valid any more when, during strong temperature inversions close to the surface, the eddy diffusivity becomes very weak. Because such strong temperature inversions do not often occur, monthly and yearly mean current densities can be computed with equation (3).

Third, the best proof of the validity of equation (3) can be found in the results of the application of this formula. The density of the current from the ionosphere to the Earth can be obtained in four different manners. (1) From the columnar resistance, r, and the potential difference between the Earth and the ionosphere, V, J = V/r. According to recent observations the mean potential difference is 260 kV. The columnar resistance, r, ranges from $8 \times 10^{16} \Omega$ m² in polar regions to $24 \times 10^{16} \Omega$ m² in polluted regions. (2) From upper air observations of the electric field and the conductivity. Above the exchange layer the current density $J = E(\lambda_+ + \lambda_-)$. (3) From direct current measurements performed with an isolated net at surface level. (4) From the conductivity and electric field observations at a height of approximately 1 metre: $J = E(1) \cdot \lambda_{+}(1)$.

In order to compare the observations of various stations the Earth was divided into three regions. I, Polar regions (Antarctic, Arctic, Greenland). II, Oceanic and continental regions above which the air is little polluted (Alaska, parts of Australia). III, Continental regions above which the air is polluted (Europe, USA).

Over fifty current density measurements at various places were compared, some of them extending over many years. The mean current densities for each group are

J in pA/m ²	I	\mathbf{m}	III
(1) Resistance: $J = V/r$	3.4	2.4	1.1
(2) Upper air: $J = E(\lambda_+ + \lambda)$	3.3	1.8	1.3
(3) Surface: direct observations	3.0		1.2
(4) Surface: $J = E(1), \lambda_{\star}(1)$	3.4	1.9	1.4

given here. Observations in mountain areas are excluded because they depend too much on local conditions.

If we should have computed the current densities at the surface from equation (2), the values would have been doubled. It is clear that this is not in agreement with the other results, so that we may conclude that equation (3) is a better approximation.

THE SOLID STATE

Chemically Stimulated Exo-emission from a Silver Catalyst

Exo-electron emission, the vaporization of very low energy electrons from solids, can be produced in a variety of ways, mechanical deformation, X-ray irradiation and chemical reaction. The emission usually decays in an exponential fashion, but, provided the excitation is not great enough to produce normal electron emission, steady exo-electron emission can be produced by steady

Chemically stimulated exo-electron emission has been found by Lohff¹ with the oxidation (or oxygen absorption) of zinc, and by Seidl² with the oxidation of copper. Exoelectron emission by some solid catalysts has also been Nassenstein and Menold³, when studying a silver catalyst used for partial oxidation of ethylene, found that exo-electron emission occurred temporarily with no additional exitation in a temperature range between 300° and 400° C. This result was confirmed by Ohashi et al.4 and they also found that the emission activity was proportional to the catalytic activity. In our investigations, we wished to see whether the exoelectrons were emitted by the silver catalyst on which

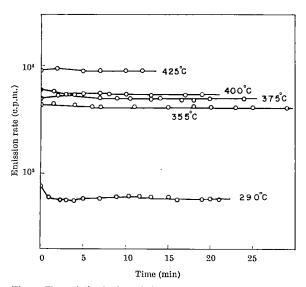

Fig. 1. The variation in the emission rate of chemically stimulated exoelectrons plotted against time. All count values plotted are the actual count minus the background count. The time scale for each curve starts at some time after the silver catalyst has reached a constant temperature.

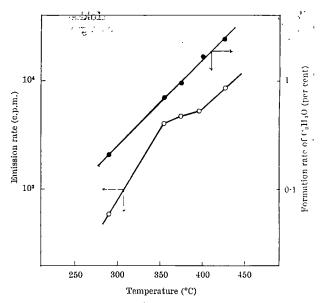

Fig. 2. The chemically stimulated exo-electron emission plotted against the rate of formation of ethylene oxide on the silver catalyst at a constant temperature in the range 250° to 450° C. The formation rate of ethylene oxide is represented as a percentage of ethylene oxide in the product gas to the percentage of ethylene in the reaction gas. The results are reproducible and stable with respect to time, provided the reaction gas flows steadily at constant speed.

partial oxidation of ethylene was taking place and to compare the emission with the formation of ethylene

The apparatus used was essentially the same as that previously reported^{4,5}. It consisted of a Geiger-Müller counter with a stainless steel cathode. Stainless steel was used, because it is catalytically inert to ethylene oxidation. An aperture at one end of the counter tube opened into a reaction compartment in which a small piece of silver wire could be heated by a small external furnace. G-M tube was kept at room temperature with a cooling jacket. The gas mixture, 91.8 per cent argon, 3.4 per cent ethylene and 4.8 per cent oxygen at 1 atm, was fairly stable as a counting gas in the temperature range examined and at an anode voltage of 2,100 V, provided the decrease in ethylene concentration due to oxidation was small. The gas mixture flowed at constant speed through the G-M tube and the reaction compartment, and simultaneous measurements of the exo-electron emission and ethylene oxide formation were made using a counting recorder and a high-sensitivity gas chromatograph.

The results are shown in Figs. 1 and 2. Fig. 1 shows the variation with time of chemically stimulated exoelectron emission at five different temperatures. In Fig. 2, the steady exo-electron emission rate has been compared with the rate of formation of ethylene oxide and demonstrates a relationship between electron emission and catalytic oxidation. It can be seen that electrons vaporize at a constant rate from the catalyst.

Blank experiments have also been carried out without the silver catalyst. In these experiments, there were hardly any counts and little or no ethylene oxide was formed in the temperature range under consideration. This excludes the possibility of ethylene oxide formation and electron liberation in the G-M tube. This leads us to believe that the electrons vaporize from the catalyst and diffuse from the reaction chamber into the G-M tube.

Our findings may provide an easy way of investigating quantitatively exo-electron emission and may also give an effective tool for the study of solid catalysts. An investigation is now in progress⁶ at this laboratory into a complete method for studying solid catalysts by chemically stimulated exo-electron emission.

We thank Professor Go Okamoto of Hokkaido University. The work was supported in part by a grant from the Ministry of Education of Japan.

Observations of a Metal-Oxide Interface

THE partial spalling that occurs when a metal is cooled after high temperature oxidation has made it possible to make direct observations of the metal—oxide interface. Scanning electron microscopy, with its large depth of focus and perspective view, has permitted this interface to be studied at high magnification in the centre of specimens away from the edges.

A high purity iron-chromium binary alloy (Cr 28 per cent) was oxidized in pure oxygen at atmospheric pressure for 6 h at 950° C. The surface was prepared before oxidation by mechanical polishing, electropolishing and brief cathodic etching. The oxide formed was chromic oxide with a small percentage of iron present, as reported by Wood and Whittle¹. On cooling after oxidation, spalling was first observed at temperatures less than 500° C, occurring violently at alloy grain boundaries, as reported previously by Howes². More extensive spalling occurred as room temperature was approached. The spalling is due to the differential contraction between the oxide and the alloy, and the broken oxide faces examined indicated brittle fracture rather than plastic deformation.

Fig. 1 shows the structure of the oxide surface, the structure of the oxide through its thickness, the face of the alloy as it existed under the oxide and the structure of the interface between the alloy and oxide. The presence of

Fig. 1. The broken face of the oxide and the alloy-oxide interface.

voids at the interface is clearly seen, and they explain the corrugated nature of the alloy face—the rough upper levels are regions where contact had been maintained between the oxide and alloy and the smooth depressions are where voids have developed.

This direct evidence of void formation at the interface verifies the outward diffusion of chromium involved in the oxidation mechanism. The considerable reduction, however, in the contact area between the oxide and alloy raises questions of how the chromium then enters the oxide, and the significance of weight gain kinetic data. It seems probable that as contact diminishes, chromium transport across the voids after evaporation, or by surface diffusion around the voids, becomes appreciable.

This investigation is continuing and will be reported more fully elsewhere.

Tetragonal and Hexagonal Iron-Manganese Carbides

During recent studies of the iron-manganese-carbon system, specimens, each weighing approximately 5 g, were carefully prepared according to predetermined compositions. The components were 500-mesh powders of 99·995 per cent pure iron and spectroscopically pure carbon and a 200-mesh powder of 99·995 per cent pure manganese. The component powders were intimately mixed by shaking, then each specimen was packed into a pure alumina crucible the end of which was closed, but not sealed, with high purity alumina cement. Each specimen was then sintered at 960° C for 110 h in a silica capsule containing helium at approximately 0·25 at m. (such time having been previously found sufficient for equilibrium to be attained¹).

Debye-Scherrer X-ray photographs were taken of at least two samples from different parts of each specimen using a 114.6 mm diam. camera. The exposure time was two hours using filtered chromium radiation, at a tube voltage of 30 kV and a tube current of 10 m.amp. For several of the specimens, it was found that photographs of samples taken from near the end of the specimen were somewhat different from those taken from the main body of the specimen, indicating the presence of composition gradients in the specimen. The presence of such gradients was confirmed by chemical analysis of two different portions of the sample.

Two specimens yielded unusual X-ray powder patterns from the main body of the specimen. The powder patterns did not indicate the presence of free iron or manganese and were not compatible with a pattern which was taken of a specimen the nominal composition by weight of which was 10 per cent iron, 90 per cent manganese (the nominal ratio of iron to manganese in all the specimens), which was prepared under identical conditions to all the other specimens. The patterns could be indexed with the aid of Bunn charts, and the crystal classes of the structures present are shown in Table 1 together with the nominal

The lattice parameters of the carbides were investigated by the use of a least squares computer programme developed by Barnet of Sydney University, and the resulting unit cell parameters are shown in Table 4. Because, in the case of the hexagonal carbide, there are only eleven observed reflexions and because three of these are broadened while another is very weak, it is felt that the quoted standard deviation may be a little optimistic in this case. Comparison, however, with the unit cell parameters obtained by Picon and Flahaut² for the tetragonal carbide Mn₄C and for the hexagonal carbide Mn₆C₂ shows that the axial ratios of Mn₄C and the tetragonal iron-manganese carbide are very similar as are the axial ratios of hexagonal $\rm Mn_6C_2$ and the hexagonal ironmanganese carbide. Furthermore, the theoretical carbon content of Fe0.4Mn3.6C is 5.17 per cent by weight, while the theoretical carbon content of Fe_{0.6}Mn_{5.4}C₂ is 6.78 per cent by weight. It is likely that a carbide of composition Fe_{0.4}Mn_{3.6}C could exist in specimen No. 3, which was observed to contain a tetragonal carbide, and that a mixture of carbides of compositions Feo. 4Mn3.6C and Fe_{0.6}Mn_{5.4}C₂ could exist in specimen No. 4, which was observed to contain a mixture of hexagonal and tetragonal carbides, by virtue of the variation in the compositions of the specimens shown in Table 1. If the carbides examined here are isomorphous with the tetragonal carbide

Table 4

Mn₄C and the hexagonal carbide Mn₆C₂, then it appears that the substitution of iron atoms for approximately 10 per cent of the manganese atoms causes a decrease of approximately 30.3 per cent in the cell volume of the tetragonal carbide and an increase of approximately 15.5 per cent in the cell volume of the hexagonal carbide. No explanation for such a difference in behaviour is apparent at this time.

We thank colleagues in the School of Chemistry, University of Sydney, for computing advice.

PHYSICS

Measurement of Electron Temperatures produced by Collisionless Shock Waves in a Magnetized Plasma

WE report measurements of the shock heating of electrons resulting from the propagation of collisionless shock fronts through a highly ionized plasma in a direction perpendicular to an initial magnetic field. The structure of the magnetic field (B_z) and the radial electric potential (V_R) within these shock fronts was reported previously and their collisionless nature deduced indirectly.

The direct measurements of electron temperature, made by Thomson scattering of laser light, were aimed at verifying two previous inferences: (a) that these shocks cannot be explained in terms of the binary transport coefficients: and (b) that the electron heating, with negligible ion heating, satisfies the conservation relations across the shock for Alfvén Mach number $M_A \leq 3.7$.

In the experiments, the shock front, driven by the fast compression of a linear Z-pinch², propagates radially inwards with velocity $V_S=2.5\times 10^7$ cm/sec through an initial hydrogen plasma, with electron density $n_{eo} \sim 7 \times$ 10^{14} cm⁻³ and temperatures $T_{eo} = T_{to} \sim 1$ eV, in various initial axial magnetic fields. A 400 MW, 20 nsec pulse from a ruby laser is passed across the diameter (50 cm) of the discharge tube at the midplane. The laser pulse is timed relative to the shock structure using an electric probe at 9 cm radius but moved azimuthally out of the optical paths. The light, scattered into the axial direction from a 1 cm length of the laser beam centred at 9 cm radius, is detected by a photomultiplier. The spectral profile of the scattered light is obtained by using interference filters with narrow pass-bands (3 to 35 Å) and high rejection ratios ($\sim 10^{-4}$).

The spectral profile, which results from Doppler broadening by the electrons, will be Gaussian if the electrons are The experimental results, covering just over a half width of the profile, fit a Gaussian curve to within ± 15 per cent and yield an electron temperature with a standard deviation of \pm 10 per cent. Systematic errors increase the possible error to \pm 15 per cent. Calculations, using these measured temperatures, show that there should be sufficient time for the electrons to thermalize before the measurements.

Three different types of shock structure arise as the Alfvén Mach number is increased $(M_A = 2.5, 3.7, 6.3)$ by decreasing the initial magnetic field ($B_{zo} = 1.2, 0.75, 0.43$ kG). At low M_A (< 3) the shock transition is sharp (width ~ $7c/\omega_{pe}$), while at high M_A (> 6) it is more than ten times broader. At intermediate M_A (~ 3.7) a double structure exists with the sharp preceded by the broad transition.

The measured electron temperatures, T_e , for $M_A = 2.5$ and 3.7 are shown in Fig. 1 as a function of time, τ , relative to the sharp transition. For $M_A=3.7$, the change in magnetic field, ΔB_z , is plotted to show the measurement of T_e within the broad transition.

The electron temperatures in Fig. 1 are compared with two theoretical predictions of the total shock heating, $T_e + T_i$, derived independently of the shock mechanism (assuming $\gamma = 5/3$). These predictions are from (i) plane geometry steady state conservation relations4 using the measured V_s , n_{so} and B_{zo} , (ii) the cylindrical collapse MHD computations⁵ (private communication by K. Hain, K. V. Roberts and D. L. Fisher) based only on the initial plasma and circuit conditions. This collapse computation has been shown previously to give good agreement with the measured dynamics of the experiments.

There is good agreement between the measured T_e and the predicted $(T_e + T_i)$ immediately behind the shock for $\bar{M}_A = 2.5$. This verifies the previous inference that the ions are not appreciably heated in this case. For $M_A = 3.7$, however, the measured Te is less than the predicted

 $(T_e + T_i)$, allowing the possibility of some ion heating. The measured electron temperatures for $M_A = 6.3$, shown in Fig. 2 with ΔB_z , are within the broad shock structure which is neither well separated from the piston nor in steady state. Consequently, neithe predictions for $(T_e + T_i)$ appears appropriate. Consequently, neither of these

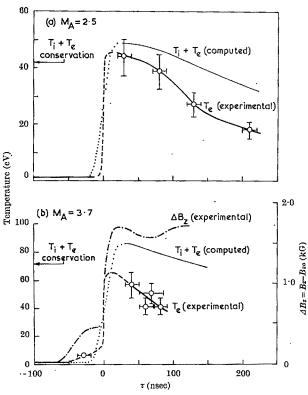

Fig. 1. Measured electron temperatures in hydrogen as a function of time and a comparison with predictions (a) $M_A = 2.5$, (b) $M_A = 3.7$, with the observed magnetic field plotted to show the slow feature.

The possibility of temperature limitation by end effects or impurities was investigated in an experiment performed in deuterium at half the number density. The dynamics were the same as for hydrogen $(M_A=2.5)$ and so the temperature should be doubled. The measured temperature, $T_e = 91$ eV for $\tau = 40$ to 60 nsec, confirmed this simple scaling and ruled out temperature limitation.

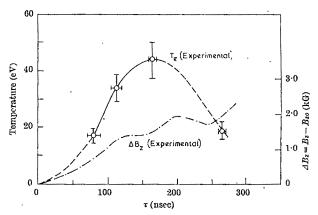

Fig. 2. Measured electron temperatures in hydrogen as a function of time for $M_A=6.3$ with the observed magnetic field plotted for comparison.

In this scaling experiment, when the electron temperature doubled, the shock width doubled while for binary resistivity it should have more than halved. Also in both these cases the binary electron-ion collision time, \(\tau_{et}\), derived from the measured T_e behind the shock, is longer than the measured shock rise time, τ_s , making such collisions ineffective; for example, in deuterium with

 $T_e = 91 \text{ eV}, \ \tau_{et} \sim 5 \tau_s.$ The measured electron temperatures are, in all cases, many times greater than those calculated from the observed structure assuming binary resistivity. Binary viscous effects are negligible. The ratios (R) of the observed to the calculated temperature rise in hydrogen are as follows: $M_A = 2.5$, $R \sim 6$; $M_A = 3.7$, broad transition $R \sim 5$, total structure $R \sim 8$; and $M_A = 6.3$, These figures demonstrate that appreciable collisionless electron heating occurs in all these shocks.

For the low M_A shock the most probable mechanism is the excitation of plasma waves by electron-ion streaming instabilities in the high current density of the sharp transition. This process provides a collective or anomalous resistance to the current. The subsequent interaction and damping of these waves can heat the electrons. A formula for the resistivity resulting from such a mechanism has been derived by Sagdeev7. Substitution of the appropriate values into this formula results in a resistivity which is more than adequate to account for the observed electron heating. Moreover, this analysis is in accordance with the absence of appreciable ion heating. The observed scaling of shock width between hydrogen and deuterium is also consistent with this theory. At present there is no satisfactory interpretation of the observed high M_A shocks.

Effect of Compression upon the Magnetic Behaviour of Magnetite in Thermal Cycles across the Magnetocrystalline Isotropic Point

The value of the first magnetocrystalline isotropic constant, K_1 , of magnetite changes at low temperature. This results in an isotropic point at a temperature T_k of about -143° C^{2,3}, where there is effectively zero magnetocrystalline anisotropy. A transition of remanence and associated memory are observed in thermal cycles across $T_k^{4.5}$. We have observed that the memory and the low-temperature moment are increased when the thermal cycles are carried out under elastic compression.

The specimen used in the experiments was a [111] bar cut from a natural single crystal of magnetite. It was $1\cdot62$ cm long and had a square cross-sectional area of $0\cdot29$ cm². Its coercive force was 9 oersted, and the saturation isothermal remanence, $7\cdot1$ emu/cm². Uniaxial compression was applied using a plexiglass device which could be mounted on a vibration magnetometer³. It was compensated for differences in thermal expansion to give a constant stress throughout the experimental temperature range. The specimen was insulated to prevent large thermal gradients. The temperature was recorded with a copper-constantan thermocouple in contact with the specimen. All experiments were carried out under external field cancellation to ±25 gammas.

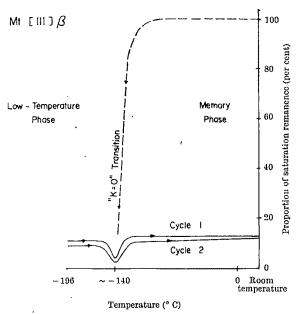

Fig. 1. Warming curves for magnetite single crystal. Sample initially saturated at room temperature.

The specimen was initially saturated at room temperature and cooled to -196° C. A control warming curve of remanence against temperature was then obtained (Fig. 1). A second cycle without re-saturation gave a slightly lower low temperature moment and memory. The experiment was then repeated after a compressive stress of 80 kg/cm² was applied at room temperature and maintained throughout the saturation process and the thermal cycles. The warming curve is shown as curve a in Fig. 2 and reveals an increase of 28 per cent and 38 per cent in the moments measured at -196° C and room temperature, respectively. The experiment was then repeated with the compressive stress applied after the saturation. This reduced the initial remanence by 14 per cent, and gave warming curve b. This procedure enhanced the low temperature moment by 41 per cent and the memory by 38 per cent.

The applied stress of 80 kg/cm² gives a small elastic strain. It is much less than the applied stress of over 500 kg/cm² required to give a stress control of magnetization in magnetite⁷⁻⁹. The experimental stress here is thus not sufficient to modify the bulk magnetization, in direction and intensity, by control of the domain pattern by bulk magnetoelastic anisotropy energy. Also, the positive bulk magnetostriction would encourage a decrease in the measured moment with compression, not the observed increase. Changes in the domain configuration, and the magnetization, should therefore be attributed to localized energy effects.

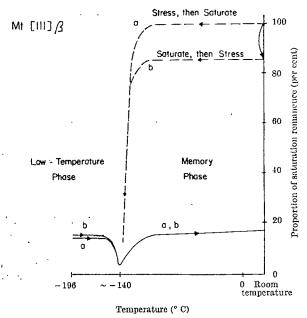

Fig. 2. Warming curves for crystal under compression of 80 kg/cm * .

a, Saturated after stressing; b, saturated before stressing.

The apparent coincidence of the transition point T_k on the temperature axis, for stressed and unstressed experiments, suggests that the magnetocrystalline anisotropy has not been measurably changed by the stress. The invariance of room temperature saturation remanence and coercive force at all stages in the stress history of the sample indicates that there has been no permanent irreversible structural change in the crystal. The applied stress, however, has increased the low temperature moment, and recovered memory, by an average of 35 per cent and 38 per cent, respectively. Thus the effectiveness of the mechanism for transferring the magnetization across the transition point has been enhanced by the stress.

These results are consistent with models of stress pinning of magnetization across isotropic points. It is suggested that the applied stress is sufficient to redistribute some existing dislocations elastically. These dislocations accumulate at local pinning points in the crystal, forming localized atmospheres, or pile-ups. These pile-ups, existing metastably under the influence of the resolved elastic shear stress, are larger than those present in the defect configuration when the crystal was not subjected to external stress. These larger pile-ups have greater stress accumulations and associated magnetoelastic energy. Our interpretation is that they then serve as more effective local pinning centres and hence nucleate a larger fraction of the moment across T_k .

The transfer of magnetization across T_k has been demonstrated to be stress-sensitive, and is interpreted as being caused by the effect of defect-associated magneto-

elastic control of the magnetization in multidomain materials.

Flow of Elastic Liquids through **Curved Pipes**

THE purpose of this communication is to outline certain interesting features which have arisen from an experimental investigation into the behaviour of dilute polymer solutions as they are made to flow under a pressure gradient through curved pipes of circular cross section.

The experimental arrangement consisted essentially of a plastic tube of circular cross section which was coiled into an anchor-ring; see Fig. 1, where a denotes the radius of the cross section of the pipe and R the radius of the central line of the pipe. The observable quantities were the pressure gradient (measured by means of transducers)

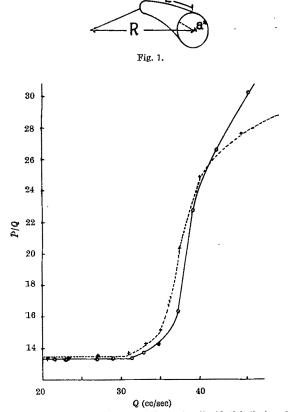

Fig. 2. Straight pipe data for a Newtonian liquid (full line) and a 0-1 per cent aqueous solution of polyacrylamide (broken line). a=0.5 cm.

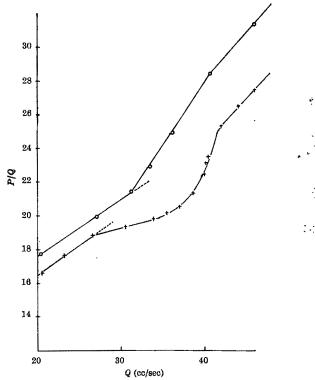

Fig. 3. Curved pipe data for a Newtonian liquid (full line) and a 0-1 per cent aqueous solution of polyacrylamide (broken line). a=0.5 cm. R=300 cm.

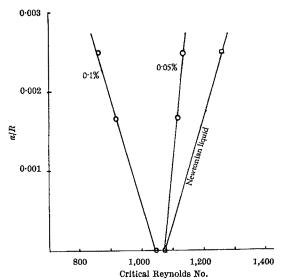

Fig. 4. Critical Reynolds number data for aqueous solutions of polyacrylamide. $a=0.5\,\mathrm{cm}$.

and the flow rate (obtainable by a conventional catchand-weigh technique). A peristaltic pump was used to create the flow and a reservoir was used to ensure that the flow was uniform and steady. All the experiments were carried out at 20° C.

Figs. 2 and 3 contain pressure gradient, P, against flow rate, Q, information for a 0.1 per cent aqueous solution of polyacrylamide and a glycerol-water mixture with a very similar viscosity. It will be observed from Fig. 2 that, in the case of the straight pipe, the data for the two liquids do not differ significantly in laminar flow, but that noticeable drag reduction occurs in turbulent flow. Of more interest in the present context is the laminar-flow behaviour of the two liquids in the curved pipe. Here the flow rate in the case of the polymer solution is noticeably higher than that for the Newtonian liquid under identical flow conditions. This is presumably because of normal-stress effects in the polymer solution, these being of no importance (so far as the flow rate is concerned) in the straight pipe. The observed trend is in agreement with the theoretical predictions of Thomas and Walters¹.

The transition region between laminar and fully developed turbulent flow is clearly discernible in Fig. 3. From this figure, it is apparent that the polymer solution is less stable than the Newtonian liquid. That the elasticity in the liquid is a destabilizing influence is further illustrated in Fig. 4, which contains "critical Reynolds number" R_{θ} data for different a/R ratios. It appears that elasticity has the greatest effect on the stability criterion when the bend in the pipe is sharpest. It will also be observed that, while curvature enhances stability in the case of Newtonian liquids^{2,3}, the opposite is possible in the case of elastic liquids.

These results are consistent with the findings of Jones and Maddock⁴ for flow in a straight pipe. We know of no theory to predict the effect of elasticity on the stability criterion in the case of curved pipes, but the observed trend is consistent with the theoretical predictions of Chan Man Fong and Walters⁵ for a straight channel

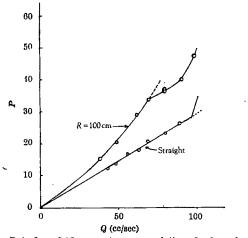

Fig. 5. Data for a 0.15 per cent aqueous solution of polyacrylamide. $a = 0.8 \text{ cm}_{\bullet}$

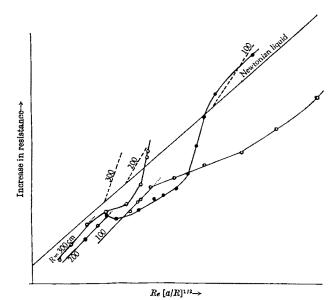

Fig. 6. Information for a 0-1 per cent aqueous solution of polyacrylamide compared with that for a Newtonian liquid. Broken lines indicate turbulent flow behaviour of Newtonian liquids. $a=0.5~\mathrm{cm}$.

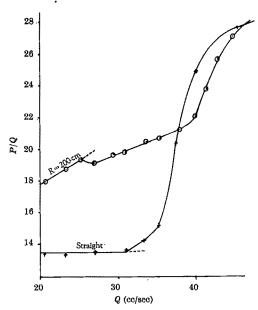

Fig. 7. Data for a 0·1 per cent aqueous solution of polyacrylamide. $a\!=\!0.5\,\mathrm{cm}.$

Fig. 5 contains pressure gradient versus flow-rate data for a 0·15 per cent aqueous solution of polyacrylamide. The interesting feature about this figure is that the drag associated with the turbulent flow of the polymer solution in the curved pipe is less than it would have been if the flow had remained laminar. This is in obvious contrast to the situation which exists in the straight pipe. Fig. 5 would seem to indicate that quite substantial drag reduction is sometimes possible in the turbulent flow of dilute polymer solutions in curved pipes. That this is so is clearly illustrated in Fig. 6, which shows that the resistance experienced by the polymer solution is always less than that experienced by a Newtonian liquid under the same flow conditions.

The substantial drag reduction associated with the flow of dilute polymer solutions through curved pipes is such as to make it easier under some flow conditions to pump these liquids through curved pipes rather than through straight pipes (see Fig. 7).

Dimensionless Form of the Double Logarithmic Equation relating Shear Stress to Shear Rate as applied to Slowly Coagulating Milk

Ostwald and Auerbach¹ were perhaps the first to point out that, for many colloidal systems, the curve of shear stress (τ) plotted against shear rate $(\dot{\gamma})$ consists of four parts. At the very lowest shear rates, if there is no yield-value, flow is Newtonian, but this is quickly followed by a region in which $\log \tau$ is linear with $\log \dot{\gamma}$ (called "Strukturviskositāt"). At a certain shear rate all the structure

is broken down and we have a Newtonian region, rather misleadingly called the "Laminarast", finally followed by a condition of turbulence around the particles called "Strukturturbulenz".

The power equation

$$\log \tau = \log K + a \log \dot{\gamma} \tag{1}$$

is not dimensionally inhomogeneous2 but has the disadvantage that the dimensions of K depend on the magnitude of a.

In a recent paper, Nedonchelle and Schutz³ have shown that in the retrogradation of starch at a constant temperature, not only is a series of straight lines obtained when $\log \tau$ is plotted against $\log \dot{\gamma}$ during the course of time (we have changed the symbols slightly) but also that $\log K$ is linearly related to a, so that

$$\log K = \log \alpha - (\log \beta)a \tag{2}$$

Combining equations (1) and (2), they get

$$\log \tau - \log \alpha = a(\log \dot{\gamma} - \log \beta) \tag{3}$$

From this it follows that a must have the dimensions of a stress and β those of a shear rate or, substituting τ' for α and $\dot{\gamma}'$ for β

$$\frac{\tau}{\tau'} = \left(\frac{\dot{\gamma}}{\dot{\gamma}'}\right)^a \tag{4}$$

This means that there must be a single point having co-ordinates $\tau':\gamma'$ at which all the log-log curves would meet if extrapolated and also that the awkwardness of the dimensions of equation (1) is overcome.

Our intention has been to enquire whether the same equations would apply to the early stages of milk coagulation by rennet, before rigidity appears, and, if possible, to test the equations over a wider range than was possible for starch.

Berridge showed that the rennet action on milk is complete in 4-6 h in the cold (2°-4° C), whereas the subsequent process of coagulation would take hundreds of hours at this temperature. Our problem was to find the right temperature at which the coagulation would proceed

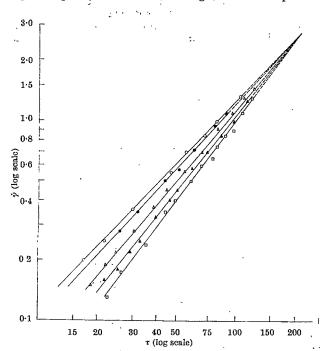

Fig. 1. Double log curves of stress and shear rates during early stages of coagulation. The five curves represent results 10 (\bigcirc), 30 (\bigoplus), 60 (\triangle), 90 (\triangle) and 120 (\square) min after reaching temperature equilibrium at 15° C.

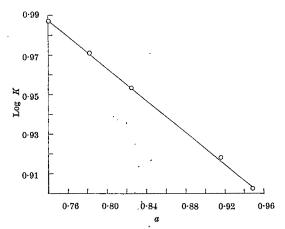

Fig. 2. Plot of $\log K$ against a for equation (2).

in such a way that there was no rigidity during the time needed to complete our experiments (about 2 h). Unfortunately, the appropriate temperature varies from one sample of milk to another. Nevertheless, we were able to carry out the experiment about four times and present here the results of one of these experiments. The τ:γ relation had to be measured within a very short space of time and this was done using a viscometer consisting of two fairly wide graduated vertical glass tubes, bent at right angles at the bottom to connect with a horizontal capillary tube, length about 16 cm, diam. 0·1 cm (see ref. 5). The viscometer was placed in a glass-sided tank full of water kept at the appropriate temperature: in the case quoted it was $15^{\circ} \pm 0.1^{\circ}$ C. One litre of skim milk was cooled to 6° C, and 20 ml. of commercial rennet at a concentration of 1:100 (final concentration 1:5,000) was The milk was stored at 2° C for 18 h. About 70 ml. of milk were then heated as quickly as possible to a temperature of 15° C and the viscometer was filled. The milk was sucked up into one of the side tubes and, on release, the head was recorded every 10 sec by means of a metronome (in another experiment, photographic recording was used which gave better data at high shear rates and showed signs of the "Laminarast", but it had no advantage for the work described here). The average head during each 10 sec interval was taken as a measure of τ and the fall in head as a measure of $\dot{\gamma}$. No attempt was made to convert to absolute units. A series of five experiments made during the course of 2 h (after which time gelation started) is shown plotted double-logarithmically in Fig. 1. It will be seen that these are good straight lines which, on extrapolation, would meet at a point. Experimentally, in fact, the "Laminarast" would be reached well below this point and at shear rates which are not independent of the age of the sample.

A plot of $\log K$ against a is shown in Fig. 2. This is reasonably linear.

We conclude that coagulating milk, like starch, follows the equations of Nedonchelle and Schutz and we suspect that they may well hold for other similar systems.

RADIOBIOLOGY

Repair Replication in HeLa Cells after Large Doses of X-irradiation

We have observed "unscheduled DNA synthesis" and non-conservative synthesis of DNA after the irradiation of mammalian cells with ultraviolet light. We have presented autoradiographic evidence that unscheduled DNA synthesis occurred in HeLa cells after X-irradiation with 5,000 r.¹. Normal semi-conservative DNA replication is considerable at this dose, so neutral equilibrium density gradient experiments to examine the molecular nature of this synthesis were precluded. In this communication we report that, after very large doses of X-rays to HeLa cells, incorporation of precursors into DNA occurs as a result of a process which has the characteristics of "repair-replication", a phenomenon which has been correlated with enhanced survival in bacteria².

HeLa S3 cells were grown and lysates prepared for density gradient analysis as previously described¹, except that incubation with pronase (500 μg/ml.) for 1 h followed the freeze-thaw lysis and preceded deproteinization with chloroform-amyl alcohol (24:1). Density gradient analyses were carried out in a fixed-angle rotor (type 40) by centrifugation at 34,000 r.p.m. and 35° C for 36-60 h in the model L centrifuge. For neutral gradients the diluent was sodium chloride-sodium citrate (0·15 molar and 0·015 molar respectively) with a pH of 7·4; for alkaline gradients the diluent was Na₂HPO₄-NaOH (0·1 molar each) adjusted to a final pH of 12·5. In both cases, the volume was adjusted to 5·9 g of CsCl, for alkaline gradients to 6·5 g of CsCl. After centrifugation five-drop fractions were collected, diluted with 0·5 ml.

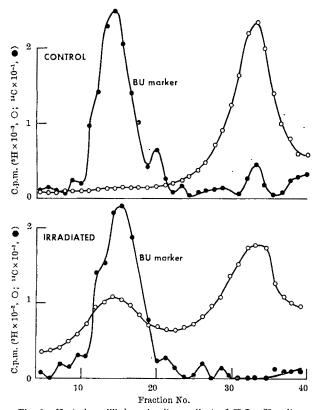

Fig. 1. Neutral equilibrium density gradient of HeLa S3 cultures labelled with BUdR (5 μ g./ml.) for 16 h, before growth for 2 h in normal medium, irradiation (or sham irradiation) with 100,000 r. and postirradiation labelling with *H-TdR (5 μ g./ml.) for 2 h. HeLa DNA labelled with *C-BUdR added as marker for hybrid DNA. O, *H counts; •, **C counts. Upper figure, controls; lower figure, irradiated.

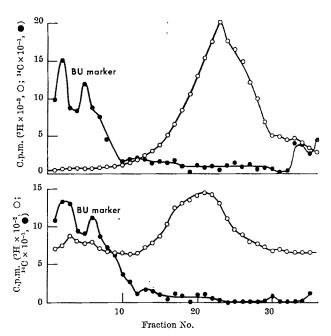

Fig. 2. Alkaline equilibrium density gradient from same cultures as Fig. 1. O, ³H counts; , ¹C counts. Upper figure, control; lower figure, irradiated.

citrate-saline and samples (0·1 or 0·2 ml.) removed for counting in a scintillation spectrometer.

In the first experiments, HeLa S3 cells were grown for 16 h in Eagle's medium containing 5 μg/ml. bromouracil deoxyriboside (BUdR). This was followed by incubation for 2 h in regular Eagle's medium before X-irradiation with 100,000 r. (300 kVp., 3,400 r./min, G. E 'Maxitron' no external filtration). Immediately after irradiation a medium containing 5 μc./ml. ³H-thymidine (³HTdR-11 c./mmole, New England Nuclear Corp.) was added and the cells incubated for 2–3 h before density gradient analysis. A ¹⁴C-BUdR-grown HeLa S3 DNA standard was added to define the position of BUdR-substituted DNA in the gradients.

Fig. 1 shows the results of a neutral density gradient experiment of this kind. In the control there is only one tritium peak, appearing at the density expected for unsubstituted DNA. In the gradient from irradiated cells, however, there is also a peak of tritium activity in the hybrid portion of the gradient at the position of the ¹⁴C-BUdR-DNA marker. That this ³H-TdR uptake is not the result of semi-conservative replication is confirmed by examination of the alkaline density gradients (Fig. 2). In these gradients the heavy, BUdR-substituted, single-stranded DNA is found in the first few fractions from the bottom of the gradient. A peak of tritium activity is present in this part of the gradient from irradiated, but not from control, cultures. Thus thymidine was incorporated into the DNA strands already formed which contained bromouracil. The appearance of tritium activity at the density of normal DNA in both neutral and alkaline gradients from irradiated cultures demonstrates that semi-conservative DNA replication also occurred in these cultures, even after this extremely high dose of radiation. The uptake of 3H-TdR into DNA of irradiated cells, however, was less than 10 per cent of that in controls.

Experiments were performed to determine whether the same process occurred in DNA of normal density. The medium on HeLa S3 cultures was replaced by one containing 5 μ g/ml. BUdR. After incubation for 1 h the medium was removed, citrate-saline added and the cultures irradiated. Incubation of the cultures with BUdR before irradiation initiates formation of hybrid

DNA and assures that subsequent semi-conservative replication in the presence of 3H-BUdR will result only in molecules which band as hybrid DNA. This eliminates the possibility of molecules with small amounts of terminal tritium that might band at or near the position of DNA of normal density. Immediately after the irradiation, a medium containing 20 μc./ml. ³H-BUdR (6 c./mmole, New England Nuclear Corp.), 5 μg/ml. unlabelled BUdR, and 10-3 molar hydroxyurea was added to the cultures. Hydroxyurea at this concentration suppresses normal DNA synthesis in HeLa S3 cells by about 98 per cent³ but has no effect on unscheduled DNA synthesis4. After incubation for 2 h, the medium was removed and the cells prepared for alkaline density gradient analysis (Fig. 3). The control shows a single tritium peak near the bottom of the gradient at the position expected for BU-substituted DNA, demonstrating that the residual DNA synthesis which occurs during hydroxyurea inhibition is of a semi-conservative kind. In the gradient from irradiated cells there is also a peak at the bottom of the gradient-again indicating a low level of semi-conservative replication occurring even during hydroxyurea treatment after 100,000 r. In this gradient, however, the most prominent tritium peak occurs at the position of normal density DNA. This demonstrates that BUdR has been incorporated into molecules of normal density at such low frequency per molecule that their density is not appreciably affected. Under the conditions of the experiment, any incorporation occurring as a consequence of semiconservative replication must result in tritium incorporation exclusively into heavy DNA strands. The observed incorporation could therefore only have resulted from insertion of ³H-BUdR into previously existing DNA molecules.

We have been unable to demonstrate unequivocally this "repair replication" at doses lower than 50,000 r., and it may be a pathological response of the cells caused by the high dose of radiation. It is more likely, however, that it occurs at low doses but is obscured by the relatively massive incorporation of tritium resulting from normal semi-conservative replication. This seems certain if one considers that unscheduled DNA synthesis, which probably results from the same primary process, has been observed at doses at least an order of magnitude lower1.

Lett et al. have recently demonstrated intracellular rejoining of single strands of mammalian DNA broken by

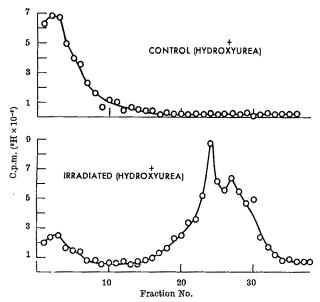

Fig. 3. Alkaline equilibrium density gradient of HeLa S3 cultures labelled with H-BUdR (20 \(\rho_c\)/ml.) in the presence of I mmolar hydroxyurea for 2 h after irradiation (or sham irradiation) with 100,000 r.

O, H counts. Upper figure, controls; lower figure, irradiated.

ionizing radiation⁵. This observation may have nothing to do with "repair replication" reported here, especially because the two phenomena probably involve different kinds of lesions (strand breakage and base damage). observations strongly suggest, however, that mammalian cells possess means by which they can repair damaged DNA. Further work to determine if "repair replication" is active and effective after low doses of ionizing radiation is in progress.

This work was performed under the auspices of the US

Atomic Energy Commission.

Erythropoiesis in Lethally Irradiated Mice grafted with Bone Marrow or Spleen Cells

In a recent paper OKunewick et al. reported that splenic erythropoiesis, defined as the 24 h uptake of iron-59 into the spleen, in mice lethally irradiated and grafted, depends on the source of the grafted cells. They found that grafting 106 bone marrow cells gave a greater uptake of iron-59 into the recipient spleen than grafting 10° spleen cells. In a second series of experiments, they found that 4×10^6 bone marrow cells grafted gave higher values than 4×10^7 spleen cells. They concluded that the relative erythropoietic activity of the spleen derived from spleen or bone marrow grafts is not a function of the number of cells administered and that the spleens are more erythropoietically active if the animals have been grafted with bone marrow as opposed to spleen cells.

During experiments to estimate the influence of drugs on the colony forming capacity of different haemopoietic tissues, we investigated the erythropoiesis in irradiated mice grafted with spleen cells and bone marrow. Our results seem to disagree with the conclusions of OKunewick et al.

Adult C3H male mice (11-13 weeks old) received a total body irradiation of 850 rad. The irradiation was performed with a Resomax X-ray machine, operating at 300 kVp and a current of 19.5 m.amp. A half value layer of 2.0 mm of copper was used. The dose rate was 31 rad/ min. In each experiment, both the bone marrow and the spleen cell suspensions were derived from the same two donor animals. The recipient animals received 5×10^4 bone marrow cells or 5×10^5 spleen cells. The cell grafting was performed within 2-3 h of irradiation. Erythropoiesis was assessed by injection of 0.5 μc. of iron-59 on the seventh day and killing on the tenth day when iron-59 was measured in 0.2 ml. of blood. The incorporation of iron-59 in the blood after 72 h was calculated by assuming a total blood volume of 7 per cent of the body weight, and was expressed as a percentage of the injected dose. After fixing the spleens in Bouin's solution, the number of spleen colonies was counted under the dissection microscope.

The results of these experiments, given in Table 1, show the relationship between the number of spleen

colonies and the iron uptake in the peripheral blood. Group A were recipients grafted with bone marrow or spleen cells from normal donor animals, whereas the donor animals of groups B and C received 1 mg/kg of hydrocortisone, respectively, 4 and 24 h before killing and preparing of the suspensions.

These data indicate that by grafting 5×10^4 bone marrow cells or 5×10^5 spleen cells an equal number of haemopoietic colonies is found 10 days after irradiation. By comparing the iron utilization in both groups, however, a higher iron utilization always showed in the spleen cell grafted animals. The packed red cell mass was determined in groups A and B and no substantial difference could be seen. These observations seem to disagree with the conclusion of OKunewick et al., who claim that spleen colonies derived from bone marrow are erythropoietically more effective than those derived from spleen cells.

Some of the grafted animals $(A_2 \text{ and } \tilde{B}_2)$ were treated with antibiotics in the drinking water (terramycin and colomycin) and, as shown in Table 2, the treated recipients have a higher iron incorporation than the untreated animals, irrespective of whether they were grafted with bone marrow or spleen cells. Even in the animals treated with antibiotics, however, the spleen grafts are more erythropoietically potent.

Table 2. EFFECT OF ANTIBIOTIC TREATMENT ON THE 72 H IRON INCORPORATION INTO BLOOD OF MICE GRAFTED WITH BONE MARROW OR SPLEEN

Figures in parentheses are number of animals used.

The difference in erythropoietic activity between the animals grafted with spleen cell and bone marrow is not understood. The fact that recipients treated with antibiotics show higher erythropoiesis may indicate that they are better protected. This may be the case in the mice grafted with spleen cells, which also received, apart from the colony forming units, some immuno-competent cells.

We can thus conclude that for an equal number of colonies in the spleen, the animals grafted with spleen cells will have higher erythropoietic activity than the mice grafted with bone marrow. The difference between these results and those of OKunewick et al. may have developed because different methods were used. A 24 h uptake of radio iron into the spleen is not as sensitive a measure of the erythropoiesis in the whole animal as the 72 h incorporation of iron into red cells.

It is likely that the radio iron content of the spleen 24 h after injection of iron-59 is a measure of iron in both erythropoietic precursor cells and storage sites.

Cytological Analysis of Chimaerism in Rats irradiated during Foetal Life

WE have shown that adult rats irradiated during foetal life show specific tolerance of maternal skin graft1. Furthermore, we also showed that the degree of tolerance was proportional to the dose of irradiation. These results corroborate those of Lengerova² and were interpreted as being caused by the passage of maternal blood cells through the placenta into the foetus.

Ramseier and Brent³ have investigated the survival of parental skin grafts in F₂ hybrids of DA and Lewis strains of rats whose mother's placentae had been irradiated during pregnancy. A marked tolerance of DA skin graft was obtained. They also thought that the passage of maternal cells through the irradiated placenta was responsible for this tolerance.

It was desirable to find out whether maternal cells really proliferated in rats irradiated during foetal life. The sex of the rat karyotype is quite easily identified, and so this marker was used in male progenies for the identification of the mother's cells in bone marrow.

Fig. 1. Karyogram of a female cell found in a male rat irradiated during foetal life.

[•] Expressed as a percentage of the injected dose.

The Sukhatme test (Fisher and Yates) was used to test significance between the bone marrow and the spleen grafts.

The combined results, spleen cell versus bone marrow, were significant P < 0.001.

^{*} Uptake of iron-59 expressed as a percentage of the injected dose. Significance test was carried out in the same way as for Table 1.

Combined results $A_1 + B_1/A_2 + B_2$: significant, P < 0.001.

Pregnant females were irradiated using a Philips X-ray machine. Irradiation conditions were as follows: 220 kV, 15 m.amp, 0.5 mm copper and 1.0 mm aluminium filters, dose rate 80-85 r./min measured in air. Target distance was 43 cm. The doses applied were 100, 200 and 400 r:; respectively. Chromosome preparations of the bone marrow of 1-2 month old male rats irradiated at between 16 and 20 days of foetal life were made, as described by Fox and Zeiss. Two 'Colcemid' injections were given 90 min apart, amounting to 1 mg/100 g of body weight each. The animals were killed 90 min after the second injection. The arrangement of chromosome pairs and the subsequent determination of the sex of the individual karyogram was carried out by the method of Fitzgeralds. Each karyogram was determined by several workers, each one not knowing the result of the others, or by a single worker arranging one karyogram several times. The karyograms scored as male or female by all workers or by one worker at least three times were assumed to be correct.

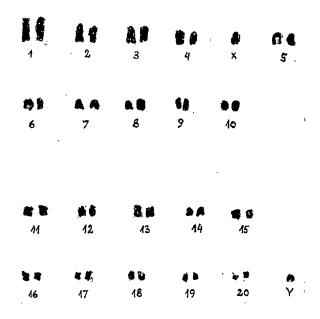

Fig. 2. Karyogram of a male cell found in a male rat irradiated during foetal life.

From the results shown in Table 1 the percentage of female cells in the bone marrow of male progeny irradiated during foetal life seems to be proportional to the dose of irradiation.

e 1. PROPORTION OF FEMALE CELLS TO THE TOTAL NUMBER OF DIVIDING BONE MARROW CELLS IN ADULT MALE RATS IRRADIATED in utero

Radiation dose (r.)	No. of tested animals	Female cells/ total No. of identified cells	Percentage of female cells
0	8	0/25	0.00
100	17	2/108	1.85
200	18	21/129	16.28
400	16	47/134	35.07

Although cytological analysis was not carried out in rats tolerant to their mother's skin grafts, the increase in the percentage of maternal cells in irradiated male progeny corresponds well with the increased tolerance after larger doses of irradiation, as described before1. Ramseier and Brent³ did not find increased tolerance after a larger dose of irradiation; however, they obtained a somewhat higher tolerance with a dose of 50 r. than with a dose of 150 r. The difference in the strength of antigens, and/or the time of exposure of foetuses may account for discrepancies between their and our results.

Chemical Study of the Radiosensitization of Micrococcus sodonensis by Iodine Compounds

It has been shown that iodoacetamide¹ (CH2ICONH2) and potassium iodide² enhance the radiation inactivation of radiation resistant bacteria. Similar results have been obtained with iodoacetic acid3,4. Dean and Alexander2 found that sensitization with iodoacetamide was observed in Micrococcus sodonensis only when the bacteria and sensitizer were irradiated together, indicating that sensitization was not caused by blocking of intracellular sulphydryl groups before irradiation or by the production of a stable toxic product. It was later demonstrated that some short lived transients of iodoacetamide were responsible for the sensitizing effect. These transients would be formed by the reaction of iodoacetamide with the radiolytic products of water. The two principal species produced by irradiation of aqueous solutions are the solvated electron (eag) and the hydroxyl radical (OH). (For a comprehensive review of this subject see ref. 6.) The aim of the present investigation was to discover which of these species was involved in producing the toxic short lived transient and to determine the nature of this transient in iodoacetamide and potassium iodide. This could be done by studying the effect of scavengers for the solvated electron and the hydroxyl radical on the sensitizing ability of iodoacetamide and potassium iodide. Our results suggest that the iodine atom (I.), produced by the OH radical attack on the sensitizers, responsible for the observed sensitization.

Micrococcus sodonensis was grown for 9 h in TGY broth 0.5 per cent tryptone, 0.1 per cent glucose, 0.3 per cent yeast extract (Oxoid) at 30° C to give exponentially growing cells at a concentration of approximately 5×10^6 These cells were collected by centrifugation, washed in 0·1 molar phosphate buffer, pH 7·0 (made with triple distilled deionized water) and then diluted to a concentration of 5×10^5 cells/ml. in phosphate buffer containing the additive in question. Samples were irradiated at room temperature under either oxygen free nitrogen or nitrous oxide with cobalt-60 γ -rays. ensure anoxia the samples were gassed for 30 min prior to irradiation. The dose rate, determined by the method of Fricke, was 2 krad/min. Estimations of viable counts of samples were made, after suitable dilutions in 0·1 molar phosphate buffer, pH 7, by the pour plate method in TGY agar. An average colony count was 200/plate and all the points plotted in Figs. 1-3 are taken from an average total count of approximately 1,500 colonies. All the chemicals used were of research grade and were freshly prepared in sterile 0.1 molar buffer solution. To

ensure comparable scavenging the concentrations of radical scavengers used were selected on the basis of their relative activities towards eaq and the hydroxyl radical.

Figs. 1 and 2 show the sensitizing effect of iodoacetamide and potassium iodide in the presence of various scavengers for eaq and OH radicals. A summary of the data is presented in Table 1. It can be seen that the addition of sodium nitrate to the bacterial suspension enhanced the sensitization by iodoacetamide or potassium iodide. Sodium nitrate is a good scavenger for the solvated electron, and so it is likely that a competitive scavenging of eag enhances the sensitizing ability of these sensitizers. On the other hand, scavenging of the hydroxyl radical by potassium thiocyanate reduces this sensitizing ability (Figs. 1 and 2), demonstrating that the transient species involved are a result of the reaction of the hydroxyl radical with the sensitizers. This is further confirmed by the fact that maximum sensitization was obtained when the bacteria were irradiated in the presence of nitrous

oxide which is known to scavenge eaq radicals, converting them to hydroxyl radicals*.

It was difficult to obtain a reproducible curve for potassium iodide. This experiment was repeated many times and although we obtained good survival curves large variations were found in the D_{0} , from run to run. This ranged from 50 to 120 krads. The curve selected for Fig. 2 having a $D_{0\cdot 1}$ of 86·3 krads represents the mean of seven runs. This variation did not occur in the presence of other additives; it is likely that this particular system is extremely sensitive to trace impurities. Experiments with different concentrations of added sodium nitrate showed that at a concentration of 10^{-6} molar sodium nitrate and 10-3 molar potassium iodide a reproducible $D_{0\cdot 1}$ of 75 krads could be obtained.

During the radiolysis of aqueous solutions of I it is known that the following reactions occur^{9,10}

$$I^- + OH \rightarrow I^- + OH^-$$
 (1)

$$I^{\cdot} + e_{\overline{aq}} \rightarrow I^{-}$$
 (2)

$$I^{\cdot} + I^{-} \rightleftharpoons I_{2}^{-}$$
 (3)
 $2I_{2}^{-} \rightleftharpoons I^{-} + I_{3}^{-}$ (4)

$$2I_2^- \rightleftharpoons I^- + I_2^- \tag{4}$$

$$2I \cdot \rightarrow I_2$$
 (5)

In the presence of sodium nitrate the following reactions also occur¹¹

$$e_{\overline{aq}} + NO_3^- \rightarrow NO_3^{2-}$$
 (6)

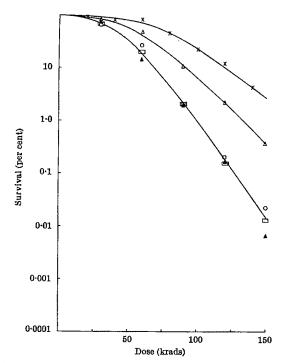

$$H + NO_3^- \rightarrow HNO_3^- \rightarrow OH^- + NO_2$$
 (7)

$$NO_2 + I^- \rightarrow NO_2^- + I^-$$
 (8)

From the survival data obtained it is clear that reaction (1) is the principal reaction leading to sensitization. I-, I2 and I are not the species involved, for they are stable and would sensitize equally well whether present during irradiation or added afterwards. Thus the transient species involved must be either I or I_a .

It has been shown that the reaction of eag with iodoacetamide is7

$$ICH_2CONH_2 + e_{aq}^{-} \rightarrow I^- + \dot{C}H_2CONH_2$$
 (9)

which is followed by reactions (1)-(5). Although the reaction of the hydroxyl radical with iodoacetamide has not been studied, it has been shown that the reaction of methyl iodide with OH radicals produces iodine atoms12, that is

$$CH^{3}I + OH \rightarrow CH^{3}OH + I. \tag{10}$$

By analogy it is expected that iodoacetamide would undergo a similar reaction, that is,

$$ICH_2CONH_2 + OH \rightarrow CH_2(OH)CONH_2 + I$$
 (11)

and I thus formed would further react according to reactions (2)-(5).

Scavenging the solvated electron in the presence of iodoacetamide will prevent reaction (9) and thus preclude the formation of the species I₂. Because N₂O greatly enhances sensitization the responsible species must be formed from the OH radical reaction, that is, the iodine atom. Thus it can be concluded that the short lived transient responsible for the radio sensitization in the presence of potassium iodide and iodoacetamide is the iodine atom formed by OH radical attack. Electron scavengers (such as NO_3) are able to enhance sensitization due to the prevention of reaction (2).

If this conclusion is correct, then methyl iodide should be a good sensitizer. Experiments using 10⁻³ molar methyl iodide are shown in Fig. 3. It can be seen that part of its sensitizing effect remains after washing the bacteria before irradiation and is probably caused by sulphydryl poisoning. The remaining effect produced by the presence of methyl iodide was small compared with iodoacetamide and potassium iodide. This is difficult to explain from a radiation chemical point of view, but other factors, such as the site at which these compounds are absorbed on to the bacteria, are also important. probably this which gives rise to the apparent discrepancy.

In conclusion, we have shown that the reaction of hydroxyl radicals with iodoacetamide and potassium iodide produces a transient which causes the observed radiosensitization. This transient is probably the iodine atom.

PATHOLOGY

Inhibition of Mouse Sarcoma 180 by a Wheat Hemicellulose B Preparation

WE have found that the polysaccharide preparation, termed hemicellulose B, isolated from wheat straw is highly active in inhibiting the growth and inducing regression of sarcoma 180 subcutaneously implanted in The polysaccharide preparation has, however, only a slight effect on subcutaneous grafts of Ehrlich carcinoma and no recognizable effect on the growth of autologous grafts of spontaneous mammary adenocarcinomas. Certain polysaccharides from higher plants have been shown to inhibit growth of transplanted tumours, but the polymers also appeared toxic and none were well characterized $^{1-13}$. Statolon from P. stoloniferium induces the production of interferon in animal cells14.

Hemicellulose A and B were isolated from wheat straw holocellulose by the extraction procedure using sodium hydroxide solution¹⁵. Hemicellulose B was water soluble. The effect on transplanted tumours was assayed using sarcoma 180 and Ehrlich carcinoma, maintained in the ascites form. Both cultures were obtained from the Sloan-Kettering Institute. Seven day old ascites were injected subcutaneously in 0.05 ml. doses into the right groin of normal Swiss albino strain mice (designated by the National Institute for Genetics, Mishima, Japan) weighing about 20 g. This produced solid tumours at the site of injection. Spontaneous mammary adenocarcinomas were those in Swiss albino mice. Tumours of suitable sizes were surgically removed as completely as possible, and a small piece returned to the site of operation as an autologous graft in order to imitate incomplete removal and ensure local recurrence.

Hemicellulose B was dissolved in sterile distilled water and injected intraperitoneally daily for 10 days starting 24 h after tumour implantation. The rate of growth of the tumour was charted weekly in the conventional manner for 5 weeks, or as long as the mouse lived in the case of spontaneous tumours. In assays terminating at the end of 5 weeks, the mice were killed and the tumours were dissected out and weighed.

Table 3. EFFECT OF REPRECIPITATED WHEAT STRAW HEMICELLULOSE B ON EHRLICH CARCINOMA (SOLID FORM)

Dose/No. of days	No. of mice	Complete regression	Average tumour weight (minmax.)	ratc (per cent)
200 mg/kg/2	10	0/10	4.0 (1.4-8.4)	-21.1
Control	10	0/10	3.3 (1.1-5.8)	
200 mg/kg/5	9	0/9	2.0 (0.9-4.0)	48.8
Control	10	0/10	3.9 (1.5-6.3)	
200 mg/kg/10	10	0/10	1.9 (0.8-2.7)	66-1
Control	10	0/10	5-6 (0-6-9-5)	
200 mg/kg/20	9	1/9	2.1 (0 -5.4)	30-0
Control	10	0/10	3.0 (0.7-5.6)	

In preliminary experiments, crude hemicellulose B from several sources was injected in 200 mg/kg doses daily for 10 days, starting 24 h after subcutaneous implantation of sarcoma 180. The tumour inhibiting effect of wheat straw hemicellulose B was striking because the tumours underwent complete regression in as many as nine out of ten mice (Table 1). Among the few remaining tumours, most were necrotized. The mice were in excellent physical condition throughout the period of hemicellulose injections with no evidence of toxicity developing. Results of further tests with reprecipitated wheat straw hemicellulose B are shown in Table 2, which also indicates the ineffectiveness of reprecipitated hemicellulose A.

Hemicellulose B of wheat straw has less effect on subcutaneously implanted (solid) Ehrlich tumour, as shown in Table 3. Complete regresssion did not occur. Similarly, wheat straw hemicellulose B was without effect on autologous grafts of spontaneous mammary adenocarcinoma. The various times necessary for the grafts to become definitely palpable and the various times of post-operative survival in twenty test mice were well within the limits of those of the controls, which were treated equally but without hemicellulose B.

The marked effectiveness of the hemicellulose B preparation against sarcoma 180 in contrast to its slight effect on Ehrlich carcinoma might imply that there is a common antigenic property between the polysaccharide preparation and a particular tumour but not with other tumours. These host-mediated effects, if existent, will be subjected to further examination.

The hemicellulose B preparation used is a mixture of polysaccharides with small amounts of other plant components present. This work does not show which of the components is active, and we intend to isolate and characterize the active component.

Carcinogenicity of Hydrazine and I,I-Dimethylhydrazine for Mouse Lung

Вотн hydrazine itself and 1,1-dimethylhydrazine are known to be hepatotoxic1-5, but neither compound was investigated for carcinogenicity until Biancifiori and Ribacchi⁶ tested hydrazine sulphate as part of a study of the mechanism of carcinogenesis by the anti-tuber-culous drug, isonicotinic acid hydrazide^{7,8}. These workers reported the induction of pulmonary tumours in 100 per cent of twenty-two female Balb/C mice which survived daily oral treatment with 1.13 mg of hydrazine sulphate for 46 weeks (total dose of hydrazine sulphate, 283 mg).

It was later reported from the same laboratory, that the incidence of hepatomas as well as of pulmonary tumours was increased in CBA mice after similar oral treatment with hydrazine sulphate. More recently, the induction of reticulum-cell sarcomas by repeated intraperitoneal injections of hydrazine dissolved in physiological saline has been described¹⁰. In this case albino mice of unspecified strain were given sixteen intraperitoneal injections at intervals of 2-3 days until total doses of 400 mg/kg (about 10 mg/mouse) had been given. Thirteen out of thirty-four mice developed tumours in between 100 and 313 days, while only one tumour of the same type was seen among sixty untreated mice observed for a year.

The aim of the experiments described here was to test a number of other hydrazines for carcinogenicity in mice. The compounds selected for test are shown in Virgin female Swiss mice were used. From the results of preliminary toxicity tests (see Table 1) in which the compounds were administered in distilled water or polyethylene glycol 400 by stomach tube, 5 days each week, doses close to the maximum tolerated dose for daily administration were decided. Groups of twenty-five mice were then treated with the six compounds by gavage at the selected dose level on 5 days each week for 40 weeks. Eighty-five untreated animals served as controls.

(1) Hydrazine NH2.NH2 (2) Methylhydrazine sulphate NH2NHCH3.H2SO4 (3) 1,1-Dimethylhydrazine NH2.N(CH3)2 (4) Phenylhydrazine NH.NH. (5) Benzhydrazide CONH.NH2 (6) p-Hydrazinobenzoic acid NH.NH.

Fig. 1. Compounds tested.

The results are given in Table 2. A higher proportion of the mice treated with various hydrazines developed histologically verified lung tumours than do the control mice, but the difference was not significant. Of the treated groups, however, two developed far more lung tumours than the rest. Both hydrazine itself and 1,1-dimethylhydrazine increased the incidence of pulmonary tumours as compared with the control groups. These differences were significant (P < 0.001 and 0.5 > P > 0.2, respectively), though strictly speaking it is not admissible to make separate comparisons with the control group. The fact that in both cases some mice bore multiple lung tumours, however, supports the view that the apparent carcinogenic effect was real. Most of the effect was seen in animals examined at post-mortem between 50 and 60 Methylhydrazine sulphate, phenylhydrazine, benzhydrazide and hydrazinobenzoic acid were without apparent carcinogenic effect. Toxicity prevented the administration of the substances which gave negative or equivocal results at dose levels comparable, on a molar basis, with those of hydrazine and 1,1-dimethylhydrazine and this may account for their failure to induce tumours.

Table 1. TOXICITY TESTS IN 15 g FEMALE SWISS MICE

Substance	Dose (five times weekly by gavage)	Solvent (0·2 ml.)	Effect

p-Hydrazino- benzoic acid	0.5 mg) 32 mg 8 mg 2 mg (Water suspension)	4/5 died day 30-280 5/5 died day 0-7 5/5 died day 0-7 2/5 died day 0-7 280) 5/5 alive day 280

The pulmonary tumours which arose in mice treated with hydrazine or 1,1-dimethylhydrazine were alveologenic or bronchiologenic adenomas or adenocarcinomas of the types which commonly arise spontaneously in mice. No other tumours attributable to treatment were observed. Marked anaemia developed, as expected, in the group treated with phenylhydrazine; this necessitated a reduction in the dose during the sixth week of treatment. No other toxic effects were observed.

It is conceivable that the activity of 1,1-dimethylhydrazine is secondary to its demethylation to hydrazine, although this would need to be more or less complete in the light of the results. Alternatively, the dimethylhydrazine may be carcinogenic itself. Unfortunately, the result of the test with methylhydrazine sulphate throws no light on this problem, because it proved too toxic to administer at comparable molarity. Further studies are

Successful Tissue Transplantation of Auxin-dependent Tumours and some of its Problems

AUTOTROPHY with respect to auxin has come to be regarded as a diagnostic characteristic of plant tumours¹⁻³. Experience shows, however, that spruce tumours in culture are heterotrophic with respect to auxin4. It was therefore decided to transplant living cells from in vitro cultures into healthy seedlings.

The methods employed for culturing primary explants of normal and tumour tissues of Picea glauca (white spruce) have been described previously. The two types of tissues were routinely grown on a medium described These explants have been maintained and transferred regularly for a number of years. In small fragments of undifferentiated, sterile tumour and of normal tissues, single cells were separated from cell clusters using an electric stirrer. Single cells were separated by filtration employing a slight modification of Bergmann's method⁶. The single cells were isolated from the suspension by a plating technique,; they grew into independent tumour and normal clones in 17 per cent of cases. The chromosome complements of each of these clones were examined as described before⁸. Almost 80 per cent of

the cells of the initial normal explant were clearly diploid, twenty-two chromosomes, and only about 12 per cent were tetraploid, while the remaining 10 per cent appeared to be an euploid and polyploid; 5 n was the highest polyploidy ever observed in these cells. Normal clones with both diploid and aborrated chromosome numbers have been established to learn the consequences, if any, of chromosomal aberrations in these cells. Chromosomal irregularities here did not seem to be associated with any other irregularities and tumorization certainly did not result from it.

Variation in chromosome number up to more than 14 n with a high percentage of an uploidy characterized the tumour cells. In spite of the initial cytological instability, each established clone remained constant indefinitely; apparently the cell population of each clone is made up of cells the chromosome complements of which remain constant when kept at 20°-21° C on the nutrient substratum described before4. Changes of the kinds and concentrations of auxins and exposure to low temperatures resulted in chromosomal changes in both normal and tumour clones and will be described later. When stable clones were established and their chromosome complements had been determined, small pieces of tumour and normal tissues were grafted on to healthy seedlings of Picea glauca. The apparent lack of uniformity in the behaviour of these transplants can be seen by analysing the data (Table 1). The fact that transplantation of different clones with the same chromosome complements often had different results, as did different transplantations employing the same clone, may emphasize the importance of the non-genetic factors, too, in determining the outcome of transplants. Of the tumour transplantations 60 per cent were completely negative and 24 per cent grew and then regressed. Only 16 per cent became permanent positive transplants. It seems significant that, however small in number, only those small fragments of tumour tissue the chromosome numbers of which had been altered developed into tumours comparable in every respect with those from which they were cultured when transplanted into healthy seedlings of Picea glauca. Thus when diploid clones isolated from tumour explants were implanted they were either not taken by the host or fused with the host without giving rise to tumours in the manner of normal tissue transplantation.

No normal tissue transplantation resulted in tumor-Although 54 per cent of these grafts were rejected, some of the normal clones with altered chromosomal complements took and these tissue implants, too, fused with the host and soon assumed the host normal growth pattern.

Table 1. CHROMOSOMAL DEPENDENCE ON TAKES OF PURE CLONE TISSUES OF $Picea\ glauca\ \mathtt{TUMOURS}$

No. of chromosomes in the cells of donor tissues	Total No. of trans- plants	No. of completely negative trans- plants*	No. of transplants taken without development of tumour	Regression transplants	Positive transplants

130	5	3	_	2	_
154	3	1	_	1	1
154	2	1			1
Total	50	30	2	12	6 (+2)

Each horizontal line represents results of grafting obtained with the same

cione. The term "take" is used to indicate the success of a transplant.

Completely negative transplants which showed no growth. Regression transplants grew temporarily but later regressed. Positive transplants which progressively grew into tumours.

These findings suggest that there are two physiologically different cytological phenomena. Chromosomal irregularities among the predominantly diploid normal cells may reflect cases where the perfect coupling of chromosome reproduction and mitosis has been disturbed by nonneoplastic factors. On the other hand, during tumorization an unknown factor (or factors) seems to render the cells neoplastic, causing chromosomal irregularies. because tumorization in these cells always seems to be associated with quantitative changes in the balance of chromosomes9. The definite lack of specificity in the chromosome numbers, even between individual cells of the same type, seems to suggest a secondary phenomenon which is the result of previous neoplastic change. These apparently secondary changes still have important consequences and could even be necessary co-factors for, or at least definite signs of, complete tumorization; clones isolated from tumorous masses with unchanged diploid chromosome complements did not show the auxindependence characteristic of these tumour cells in culture. These findings also reveal that in a given mass of tumorous tissues in vitro there are always a number of completely normal cells. This may explain why different investigators working with different isolates of tissue masses of Picea glauca, rather than with populations of single isolates, had arrived at different results10,11. Thus the behaviour of different isolates seems to be largely determined by the number of normal cells actually present in a mass of so-called tumour tissue, and results may be more uniform and meaningful where single cell cultures are being studied. Why different clones behave differently. and why inocula of the same clone behave differently, is far from understood.

Another difficulty is that the existence of a particular cell with an irregular chromosome complement does not prove that it was induced by a neoplasm. quite clearly, true neoplastic cells of Picea glauca are no longer diploid.

IMMUNOLOGY

Increase in Antibody-forming Cells of Neonatally Thymectomized Mice receiving Calf Thymus Extract

DEVELOPMENT of the mammalian lymphoid system and attainment of full immunocompetence have been shown to depend on the presence of the thymus during early The possibility has been considered that the

multiple functions of the neonatal thymus are effected not only by migration of viable thymocytes or cells preformed elsewhere which become competent within the environment of the thymus, but also by means of a diffusible substance secreted by the thymus and affecting differentiation of lymphocytic cells outside this organ. Evidence for such a humoral mechanism has accumulated from studies of the ability of thymic tissue contained within cell-tight diffusion chambers to prevent the deficiencies resulting from surgical removal of the thymus. Specifically, mice implanted intraperitoneally with chambers allowing passage of fluids but not of intact cells showed neither depletion of lymphocytes of peripheral blood and lymphoid organs nor characteristics of the wasting syndrome which follows thymeetomy of newborn animals4. Furthermore, the ability to form antibodies in a primary response against sheep erythrocytes was, to a large extent, maintained, as was the capacity of neonatally thymectomized mice to reject skin homografts. The non-cellular nature of this thymic substance has been confirmed by studies of the restorative effects of a cellfree component extracted from thymus of xenogeneic In neonatally thymectomized mice, wasting disease was prevented and the normal lymphocyte population of peripheral blood and spleen was maintained by injection of such extracts^{7,8}. Furthermore, the abilities of such mice to reject both skin grafts and tumours were partially restored and graft versus host reactivity was partly returned to the spleen cells of thymectomized mice by calf thymus extracts^{9,10}.

The first steps towards identification of this thymic hormone have indicated that the bovine thymic extract prepared in this laboratory is protein, the most active component in stimulating DNA synthesis in lymph nodes of thymectomized mice being in that fraction precipitated by ammonium sulphate at 20–40 per cent saturation¹¹. In addition, this preparation was also effective in restoring the graft versus host response of spleen cells from thymectomized animals¹². We have investigated the ability of this fraction of thymic extract to restore the primary immune response of neonatally thymectomized mice against sheep erythrocytes. The haemolysin response was evaluated by the Jerne plaque assay¹³ in order to determine the number of functioning antibody producing cells.

Extracts of calf thymus and calf kidney were prepared as described previously¹¹. The thymus extract tested in this experiment was that fraction precipitated by ammonium sulphate at 20–40 per cent saturation, and was adjusted to a protein concentration of 5 mg/ml., while total kidney extract was used as control at a concentration of 10 mg of protein/ml. The extracts were administered according to the schedule in Table 1.

Inbred C3H/eb mice received 0.05 ml. of extracts intraperitoneally on the first day of life and again on the seventh day, with the aim of overcoming the antigenic effects of calf extracts. Thymectomy was performed on the third day by an adaptation of Miller's technique¹⁴ and completeness of thymectomy was confirmed, when the mice were killed, by inspection and also histologically. When 2 weeks old, animals of one group were implanted subcutaneously with whole thymuses from 1–2 day old

syngeneic donors. From 2 weeks old, animals of two other groups received intraperitoneal injections of thymus or kidney extract three times a week. Injections were terminated a week before immunization. When the animals were 9-13 weeks old antibody-plaque forming cells of the spleen were estimated according to the procedure of Jerne¹³ with the following modifications. Four days after intraperitoneal injection of 4×10^8 sheep erythrocytes, the spleen of each mouse was dispersed by pressure, first through a wire mesh and then through a 27 gauge needle, into Hanks solution. Samples (0.1 ml.) containing the desired number of cells were added to 1 ml. of 0.7 per cent Difco' agar + 0.56 per cent DEAE dextran dissolved in Hanks solution at 47° C, and 0.1 ml. of 4×10^7 sheep red cells. Duplicate quantities of spleen cells and antigen were mixed and layered on a base of 1.4 per cent agar in Hanks solution in 2 in. Petri dishes. After 1 h at 37° C, the plates were re-incubated for 0.5 h with guinea-pig complement diluted 1:25 in Kolmers saline. Unstained plaques were counted under the dissecting microscope. Each spleen was weighed and the number of spleen cells was estimated from a dilution of 1:100. In addition, before killing for the plaque assay, serum was collected from blood of the retro-orbital sinus of some of the mice. The haemolysin titre of this serum was measured as follows. Doubling dilutions of serum (0.1 ml. inactivated at 56°C) were made in saline (0.1 ml.). After addition of 1 per cent sheep erythrocytes (0·1 ml.) and guinea-pig complement diluted 1:20 in Kolmers saline (0.1 ml.) the tubes were incubated at 37° C for 0.5 h. The reaction was stopped with saline citrate and 100 per cent haemolysis evaluated the next day

The impaired splenic haemolysin response of thymectomized animals is evident in the results shown in Fig. 1. It can be seen that extract of kidney, used as a control of bovine protein, had no restorative effect on the deficiency caused by thymectomy. In contrast, extract of thymus elicited an increase in the number of competent spleen cells in five of the ten animals tested to a response approximately five times that of thymectomized controls. Although the magnitude of this restoration is small in comparison with normal function, it represents a considerable amount of the repair achieved by subcutaneous grafts of whole thymus. These results indicate that the spleen cells responsible for production of haemolysing antibodies are under the influence of a thymic hormone, and confirm previous findings based on experiments with diffusion chambers5.

A depression in the primary haemolysin response of neonatally thymectomized mice could result from a decrease in the number of cells producing antibodies, or it could reflect diminished activity of a normal number of cells among other possibilities. By the use of Jerne's plaque assay it was possible to consider the first alternative specifically, and it is clear that these results support previous evidence of a decrease in the number of functional cells¹⁰. On the basis of comparison of plaque size, it has been suggested that the antibody output of each cell is not reduced after thymectomy¹⁵. A comparison of the haemolysin activity of serum with the number of antibody forming cells in the spleen (presumably the chief site of haemolysin formation) suggests, however, that the

quantity of antibody in a cell may also be reduced by thymectomy (Table 2). From a small sample this value appears to be increased under the influence of thymus extract.

Because the number of functional cells is reduced by thymectomy and partially restored by thymus extract, it is of interest to determine whether this action of thymic hormone was exerted on the total complement of nucleated spleen cells or more specifically on a particular type of cell. As can be seen in Table 3, the increment in functional antibody producing cells does not result from a general spleen cell proliferation; this suggests either a specific proliferation of target cells or the activation of already existing cells by thymus extract.

The limited extent of restoration of the spleen cell haemolysin response mediated by the thymus extract

Table 2. RELATION BETWEEN CIRCULATING ANTIBODIES AND NUMBER OF ANTIBODY-FORMING CELLS OF SPLEEN

Treatment	Reciprocal of titre of serum hacmolysins/10 ³ plaque-forming cells of spleen	Ratio of antibodies/cells
Intact	256 / (8)	7.8

Thymectomy + thymus extract	+174	+ 65	
Thymectomy + thymus implant	+856	+22	

Value for each group is average of between seven and ten animals.

requires an explanation in view of the greater degree of improvement that was found in diffusion chamber experiments, and the qualitatively stronger influence of the same thymic preparation on other immunological responses¹⁰. The chain of events leading to antibody production, as distinguished from homograft rejection and graft versus host reactivity, may involve more than one type of lymphoid population. One of these populations may be dependent on a thymic component which is not optimally active in this extract. Before this explanation can be considered, however, the possibility must be eliminated that xenogeneic extracts of bovine origin present a competitive antigenic challenge to the restored cells. In support of this notion are the results of preliminary experiments in which complete calf thymus extract (containing many additional proteins) administered from 2 weeks of age failed to enhance the spleen cell plaque response of thymectomized mice, and parallel treatment with complete extract of calf kidney even depressed the response. Investigation of these possibilities must await further purification of the active component of thymus extract or, alternatively, development of a system for the testing of syngeneic material. The significance of the present results, however, lies in the indication that a humoral factor extracted from thymic tissue restores the capacity to form haemolysing antibodies to a portion of the spleen cells of neonatally thymectomized mice.

CYTOLOGY

Visualization of Human Somatic Chromosomes by Scanning **Electron Microscopy**

Some structural details of human somatic chromosomes cannot be examined by light microscopy because of their size and because of insufficient contrast after staining, nor can they be viewed by phase contrast. Barnicot and Huxley¹ attempted to get more information about fine structure from transmission electron microscopy. They stained unsectioned chromosomes with uranyl acetate and lead hydroxide, but the structure appeared somewhat diffuse and in spite of a slight gain in the clarity of the

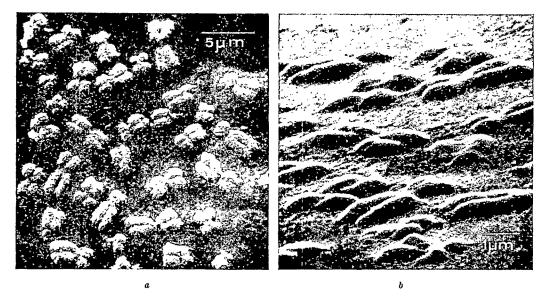

Fig. 1. a, Metaphase plate at a magnification of 2,800 and tilted to an angle of 30° from the normal plane to the direction of observation.

b, The same metaphase plate as a at a magnification of 9,600 and tilted to 80°.

image no additional features were revealed. Perhaps an ordered structure in the unfixed chromosomes was lost by the preparative procedures. Because of its tedious nature this technique is useful for special purposes rather than for routine examination.

A different aspect of human chromosomes was examined by electron microscopy², but no technical data were given. ("La structure fine des chromatides est pour l'instant à la limite des possibilités".)

In light microscopy as well as in transmission electron microscopy the image is made up of beams which have penetrated the chromosomes. The scanning electron microscope, however, which was developed recently, shows an image of the surface of the object which is being scanned. The highest resolution of about 200 Å exceeds by far that of light microscopy. A further advantage of microscopy in the study of human chromosomes is in the operation of the instrument: specimens of about 10 mm in diameter can be moved, in a plane normal to the electron optical axis, in two orthogonal directions. Because of the great depth of focus the microscope gives a three dimensional aspect of the object. By tilting and rotating, the specimen can be put in the desired position. A particular preparation is necessary only in the case of electrically non-conducting specimens in order to prevent an electric charge accumulating on the surface. This was done by overlaying them with a thin film of evaporated aluminium.

For our first attempt to visualize human chromosomes by scanning microscopy we used metaphase chromosomes from cultured lymphocytes, with a 1 per cent solution of sodium citrate to produce hypotonic shock and acetic ethyl alcohol (1:3) as fixative. The supporting slides were examined under a low power light microscope and areas of about 10×10 mm² with adequate numbers of metaphases were cut with a diamond. Preliminary results of this simple technique are shown in the micrographs.

The metaphase plate seen in Fig. $1a~(\times 2,800;$ tilting angle 30°) shows a few details of the surface structure of the chromatids. The centromere region as well as the satellites are definitely lower than the arms of the chromosomes. Some of the chromatids exhibit a fine cleft which separates the half chromatids, as occasionally observed by light microscopy in stained specimens or by phase contrast³. We do not know yet to what extent this surface is coated by a layer of fixed residual cytoplasma.

By tilting the same metaphase plate to an angle of 80° (Fig. 1b; $\times 9,600$) it can be estimated that the thickness

of the chromosomes varies from about 1100 Å at the centromere to a maximum value of about 2600 Å in the mid portion of the long arms, as long as the thickness of a layer of residual cytoplasma is uniform on the slide and on the chromosomes. A real diminution of the chromosomal substance can be observed at the telomere, centromere and satellite regions.

In further work it will be necessary to examine chromosomes prepared in different ways⁴. New preparative procedures must be developed to give "naked" chromosomes which are not grossly modified and no essential alterations must be produced by fixation.

This work was supported by the Deutsche Forschungsgemeinschaft which provided the scanning electron microscope 'Stereoscan' to Professor Pfefferkorn, for whose help we are grateful.

Reproductive Death of Irradiated Cultured Mammalian Cells and its relation to Mitosis

A close relationship between mitosis and cell death has been demonstrated in rat retina¹, and similar observations have been made on various other cell systems. This type of cell death has often been called "mitotic death" or "division death", emphasizing its relationship to mitosis or division. Lately, this type of death has been called "reproductive death", stressing loss of reproductive integrity². It should be mentioned that all terms, including "metabolic death"³, express only part of the characteristics of cell death, but none to the satisfaction of everyone. Knowing the shortcomings of these terms,

"reproductive death" will be used, for the sake of convenience, for this type of cell death.

Evidence which suggests a close relationship between mitosis and cell death can be divided into three classes. (a) The radiation dose needed to kill cells at and after the first post-irradiation mitosis (reproductive death) was, in most rapidly dividing cells, substantially less than that needed for interphase death of these cells4,5. (b) The appearance of dead cells was associated with the appearance of mitotic cells3,5,8. In many situations, the fraction of dead or dying cells increased at the time of the first post-irradiation mitotic peak^{1,6-11}. (c) The conditions which modified the mitotic index of the cell population affected the appearance of dead cells in the tadpole^{8,10}. For example, low temperature delayed the appearance of the first post-irradiation mitotic peak as well as the appearance of dead cells¹⁰. The second dose of radiation decreased the mitotic index as well as the fraction of dead cells9.

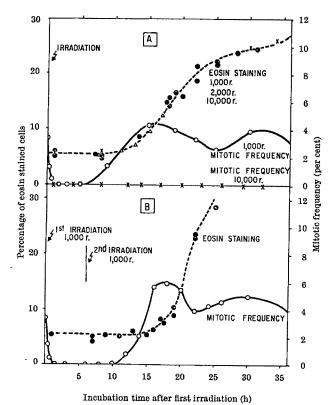

Fig. 1. Changes of the mitotic frequency and the percentage of cells stained by eosin with time in the irradiated cell population. A. The cell cultures were irradiated with a single dose at 0 h. − − − , Eosinstaining curve (♠, cells irradiated with 1,000 r., ∆, 2,000 r. and ×, with 10,000 r.). —, Mitotic frequency (○, irradiation with 1,000 r. and ×, t10,000 r.). B. The cell cultures were irradiated with doses of 1,000 r. at 0 and 6 h. − − − , Eosinstaining curve; —, mitotic frequency. The percentage of cells stained with eosin in the non-irradiated control is 5.0 per cent ± 0.8 per cont and the mitotic frequency of the non-irradiated control is 3.4 ± 0.1 per cent.

In suspension culture of mouse leukaemic cells, L5178Y, our previous work showed that, after a lethal dose of gamma radiation, the sudden increase of cells which stained with eosin (dead or dying cells) occurred shortly after the first as well as the second post-irradiation mitotic peak¹¹. This suggested that many of the lethally irradiated cells die at G₁ after completion of one or more mitoses¹¹.

The present communication provides further evidence to show that the post-irradiation mitotic peak is positively related to reproductive death of mouse leukaemic cells, L5178Y, in culture.

A suspension of L5178Y cells in the exponential growth phase was irradiated with 1,000 r. of gamma radiation from a cobalt source. After irradiation, the frequency of mitosis (percentage of cells in M) and of cosin staining (percentage of dead or dying cells^{11,12}) was determined as a function of time. Immediately after irradiation, there was a complete G_2 block (which prevented cells passing from G_2 to M). After 6 h, the block disappeared and the cells began to enter M with a resulting rise in mitotic frequency. The first mitotic peak occurred 15 h after irradiation. The increase in the percentage of cells stained with eosin began 10 h after irradiation and reached a maximum after 20 h (Fig. 1A).

In order to delay the appearance of the first mitotic peak, a second dose of gamma rays (1,000 r.) was given 6 h after the first irradiation (just before the disappearance of the first G_2 block). The second dose at 6 h caused not only a further delay in the appearance of the first mitotic peak, but also a comparable delay in the appearance of cells stained with eosin (Fig. 1B).

To show that such delay of both mitotic peak and cells stained with eosin is not caused by the higher dosc of radiation, 2,000 r. was given initially instead of the first dose of 1,000 r. Fig. 1A showed that the 2,000 r. produced the eosin-staining curve superimposable on that of the first 1,000 r. alone.

It should be mentioned that the cells irradiated with 10,000 r. died similarly to those that received 1.000 r. but that they did not show any clearly distinguishable mitotic peak (Fig. 1). We observed, however, the appearance of meshed nuclear structures in the post-irradiation period of 15–20 h. This could be a feeble attempt of the severely damaged cells to undergo mitosis. The other reason why cells irradiated with 10,000 r. are said to die of reproductive death is that it was observed that more than 35,000 r. was necessary to kill L5178Y cells by interphase death (unpublished work of Goldstein and Okada).

These observations constitute another piece of evidence that the post-irradiation mitotic peak is closely related to death of L5178Y cells and suggest that the passage of lethally irradiated L5178Y cells through M is an essential step for the cells to die at G_1 . The present observations agree with the idea of chromosome aberrations being the principal cause of reproductive death in cultured mammalian cells (see, for example, refs. 13 and 14).

GENETICS

Abnormal Distribution of Haemoglobin Genotypes in Negro Children with Severe Bacterial Infections

SEVERE pneumococcal infections (meningitis and/or septicaemia) in children in this department have been unexpectedly frequent in cases of sickle cell anaemia (SCA). We have investigated this situation by examining the distribution of haemoglobin genotypes in a group of children with acute, generalized bacterial infections.

All records of patients hospitalized in our department from 1959 until December 31, 1966, with bacteriologically proved acute meningitis and/or septicaemia were reviewed. Salmonella infections were excluded because of their particular tendency to cause chronic osteitis in patients with sickle cell anaemia.

Altogether 265 cases were examined, of which sixtynine had to be rejected because the haemoglobin genotype had not been determined. Haemoglobin electrophoresis was not carried out either because the young age of the patient made paper electrophoresis unreliable, or because the patient died quickly after admission, before an appropriate blood specimen had been taken. remaining 196 cases the haemoglobin genotype was known and the diagnosis of septicaemia and/or meningitis was substantiated by a positive bacteriological culture from the blood, from the cerebrospinal fluid or from both.

Haemoglobin genotype was determined routinely by paper electrophoresis with a tris-barbiturate buffer. After November 1964 agar gel electrophoresis with citrate-citric acid buffer was used in the case of children less than 6 months old. The last method gives clear-cut results, even in the newborn. Bacteriological diagnosis was made according to standard cultural and immuno-logical techniques. The distribution of haemoglobin logical techniques. genotypes in the patients was compared with the expected distribution by standard statistical methods.

The distribution of haemoglobin genotypes was similar in patients with septicaemia and in patients with meningitis, so the two types of infections were connected. The causative organisms fell into five groups: pneumococci (forty-five cases), coliforms (fifty-seven cases), staphylococci (thirty-three cases), Haemophilus influenzae (twentyfive cases) and a miscellaneous group (thirty-six cases) including Neisseria meningitis, streptococci, proteus group, pseudomonas group, clostridia, and Flavobacterium meningosepticum. The distribution of the haemoglobin genotypes for the five bacterial groups is shown in Table 1.

Table 1.	DISTRIBUTION	OF HAEMOGLO	BIN GENOTY	PES
Bacterial groups	AA	AS	ss	Total
Pneumococci	18 (40·0%)	(8·9%)	23 (51·1%)	45 (100%)
Coliforms	40 (70·2%)	8 (14·0%)	9 (15·8%)	57 (100%)
Staphylococci	20 (60-6%)	7 (21·2%)	6 (18·2%)	33 (100%)
H. influenzae	19 (76·0%)	(12·0%)	(12·0%)	25 (100%)
Miscellaneous	28 (77·8%)	(11·1%)	(11·1%)	36 (100%)
Total	125 (63·7%)	26 (13·3%)	45 (23·0%)	196 (100%)

Haemoglobin S is the only abnormal haemoglobin known to be present in a significant frequency in the Bantu population of Kinshasa (formerly Leopoldville). The incidence of the sickle cell trait (SCT) in 488 adult women living in Kinshasa has been found to be 26.6 per cent (unpublished work of Vandepitte, Van Baelen, Cornu and Eeckels); the local incidence of sickle cell anaemia in a group of 1,000 newborn babies was 20 per thousand. The figures agree well with each other: assuming an equal frequency of sickle cell trait of 26.6 per cent in adult males and females, it can easily be calculated that the

frequency of the genotypes AA, AS and SS in a newborn population has to be 75·1 per cent, 23·2 per cent and 1·7 per cent, respectively. This distribution can be considered to modify itself during childhood to reach in adults the figures 73.4 per cent, 26.6 per cent and

The average age of our 196 cases of severe bacterial infection was 26 months. At that age the exact distribution of the three haemoglobin genotypes is unknown. For the purpose of this communication, it will be assumed that it is still the same as at birth, namely, 75.1 per cent AA, 23.2 per cent AS and 1.7 per cent SS. Compared with this expectation, the observed distribution is markedly abnormal for each bacterial group taken separately as well as for the whole 196 cases. The observed frequencies for the genotype SS are constantly greater than expected, whereas the observed frequencies for AS are constantly lower, except in the case of the staphylo-This abnormal distribution is most prococci group.

nounced in the pneumococci group.

Using the Kolmogorov-Smirnov test¹, the distribution observed in the pneumococci group can be shown to differ significantly from the expected distribution (P < 0.01). The same is true for the total of all groups (P < 0.01). There is, however, some doubt as to the homogeneity of this total group; the distribution observed in the case of pneumococci differs significantly from the distribution observed in the total of other bacterial groups (P < 0.01). After eliminating the pneumococci group from the total, the distribution of haemoglobin genotype in the 151 remaining cases can be shown to differ from the expected distribution in a way which is probably significant (0.01 < P < 0.05). Finally, it must be noted that when only the AA and AS cases are considered, the differences between the observed and expected frequencies of both genotypes are not statistically significant, neither in the pneumococci group nor in the total of the remaining cases.

In forty-five cases of pneumococcal septicaemia and meningitis, the proportion of patients with sickle cell anaemia was found to be significantly greater than expected. The only explanation which presents itself is an abnormally high sensitivity of children with sickle cell anaemia to pneumococcal infections. A markedly increased incidence of meningitis, mostly caused by pneumococci, has been described2 in patients with sickle cell anaemia. In 151 other cases of acute bacterial meningitis or septicaemia caused by various germs (excluding pneumococci), the proportion of cases of sickle cell anaemia is also greater than expected; the difference is probably significant. Although apparently to a lesser degree, as with pneumococci, cases of sickle cell anaemia might also present an increased sensitivity to other bacteria.

In all bacterial groups observed, except staphylococci, the proportion of sickle cell trait is unexpectedly small. Although the difference between observed and expected frequencies is not statistically significant, the possibility that sickle cell trait is linked with a lowered sensitivity to bacterial infections must be considered.

We thank Professor A. Pieters for his help with the statistical analysis, and Professor H. Lehmann and Professor J. Vandepitte for helpful discussions.

Eradication of Culex pipiens fatigans through Cytoplasmic Incompatibility

Culex pipiens fatigans is the chief vector of filariasis in south-east Asia. Urbanization has often caused the numbers of this mosquito—and with it the danger of filariasis infection—to increase alarmingly¹. The natural vigour, tolerance and fast development of resistance to insecticides of this mosquito necessitate the development of other control methods, and cytoplasmic incompatibility² seems to be an ideal means.

Crossing between members of allopatric populations of the Culex pipiens complex can produce four different results. Most populations will produce normal offspring in reciprocal crosses, while some give offspring in one direction and embryos which will not hatch in the opposite direction. Other crosses are infertile in both directions. This lack of offspring is due to cytoplasmic incompatibility³, which is inherited cytoplasmically. It remains constant for indefinite numbers of generations in the female line. In an incompatible cross the sperm is blocked before it can fuse with the haploid egg nucleus, and if the embryos develop they do so from the haploid egg nucleus and die before hatching (unpublished work of E. Jost).

Twenty different crossing types are known in the Culex pipiens complex, and it is possible to specify at least one, sometimes several, strains of the complex which are incompatible with a certain population of Culex pipiens anywhere in the world. Desirable genic traits can be introduced into an incompatible strain without changing the cytoplasmic incompatibility, and so strains from temperate regions can be adapted to tropical environments.

Release of incompatible males into a natural population should be suitable for the control of *Culex pipiens*. Cage experiments show that females cannot discriminate between normal and incompatible males, and the competitiveness of males depends largely on nutritional conditions during larval development. Cage populations with an initial ratio of incompatible and normal males of 1:1 have been eradicated after three or four generations.

The World Health Organization sponsored a pilot experiment at the Filariasis Research Unit at Rangoon. A strain of Culex pipiens fatigans with the cytoplasm from a strain from Paris and the genome from a strain from Fresno, California—considered to be better adapted to ecological conditions in Burma than the pure Paris strain—was used. During August to October 1966, males were tested for incompatibility with females from twenty-five natural populations in Rangoon and its surroundings.

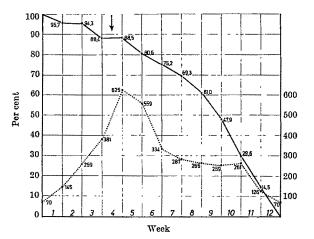

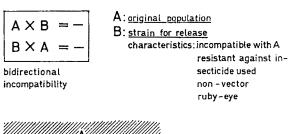

Fig. 1. Eradication of *C. fatigans* in the village of Okpo, Burma, February-May 1967. ——, Daily average percentage of hatching rafts per week 1-12; , daily average number of egg rafts per week 1-12.

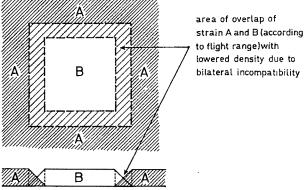

Fig. 2. Self-operating system. Replacement of strain A by strain B with subsequent equilibrium between A and B.

These females laid a total of 1,472 rafts with 130,445 eggs. Only 180 larvae hatched (0·14 per cent).

The field work was carried out at Okpo, a village about 10 miles north of Rangoon, surrounded by completely dry rice fields during winter. The size of the mosquito population was estimated to vary from a minimum of 2,000 males and 2,000 females to as many as 10,000 males and 10,000 females on a given day, depending mostly on fluctuations in the number and extent of breeding places.

Incompatible males were released between February and May 1967 (Fig. 1). From March 16 until May 6, 5,000 incompatible males were released daily. Because of the initially small number released the percentage of non-hatching rafts from incompatible crosses remained low (week 1-4, 4·3-11·6 per cent). Soon after the release of the optimum number of 5,000 incompatible males/day (arrow in Fig. 1) the percentage of inviable rafts increased to an average of 19.4 per cent (fifth week, March 21-27) in spite of an almost ten-fold increase in the size of the population during the first 4 weeks (seventy rafts/day during the first week, 625 rafts/day during the fourth week). During the next seven days (March 28 to April 3) a slight increase to 24.8 per cent occurred; during the following week (April 4-10) 30.7 per cent was observed. From then on the percentage of inviable rafts increased more rapidly. It reached 39.0 per cent during April 11-17 (week 8) and 70.4 per cent during April 25 to May 1 (week 10). A new wave of higher production in the breeding areas, beginning in week 10, was obviously cut off by the high percentage of non-hatching rafts. During May 2-8 (week 11) the percentage increased to an average of 85.5 per cent and finally, on May 9 and 10, 100 per cent inviable rafts were obtained. The production of new larvae was therefore stopped and no more adults were expected to emerge after about 10 days. Unfortunately, the monsoons started on May 11 and the experiment had to stop.

The results of this experiment show that the incompatibility principle can operate in nature and that, after the release of an adequate number of incompatible males, a C. p. fatigans population was eradicated in about 3 months or five or six generations. If in the future a population in an extended area is completely suppressed, the problem of filling the vacuum created could be serious. With the removal of C. p. fatigans with its high

density in most breeding places an opening will be available for aquatic insects with similar ecological requirements. Another species of mosquito could come to occupy the niche. It might be harmless or a vector of the same importance. A strain of C. p. fatigans unable to transmit filariasis, or even a strain with no desire to bite man, could be developed and liberated to fill the empty niche. This strain should be incompatible with the surrounding population. Fig. 2 shows a model for the eradication and replacement of a natural population (A) based on the possibility of creating an equilibrium between a new population (B) and the surrounding original population (A). The model requires the replacement strain B to be incompatible with the original population A in two reciprocal crosses. Strain B must be a non-vector, and it would be useful if it were also resistant to an insecticide if such is used initially to depress strain A. A visible, nondeleterious genetic marker, for example, ruby-eye, included in strain B could be very helpful in further observations of whether equilibrium between A and B is maintained.

This work was supported by the World Health Organization and was carried out while I was a consultant to their Vector Biology and Control Unit.

BIOLOGY

Isolation of Rabies Virus from Fruit Bats in Thailand

THE transmission of rabies by bats was first reported in 1921 (ref. 1). Vampire bats (Desmodus rotundus murinus) have been found to be an important carrier of sylvatic rabies in South America2, and they have been known to shed the virus in their saliva for long periods of time without apparent illness3. Since 1953, when the first rabies isolate from bats in the United States was made from a yellow bat (Dasypterus floridanus) in Florida, there have been more than five hundred isolates from bats in at least thirty-six States4. A survey of the literature has failed to reveal reports of rabies in bats in south-east Asia, and publications of the World Health Organization^{5,6} state that surveys of bat rabies in Asia have been consistently negative. The same statement about bat rabies in Europe, however, was refuted by Pitzschke⁷, who isolated rabies virus from a wide-winged bat (Epitescus serotinus) in Thuringia, Germany. The high prevalence of rabies in Thailand and the dense bat population prompted us to investigate the disease in bats in this area.

Seventy-nine dog-faced fruit bats, Cynopterus brachyotis, were trapped in Kanchanaburi, Thailand, and their brains were removed and examined by the fluorescent antibody technique. Two were found to be positive and weanling mice were inoculated intracranially with a 20 per cent suspension in phosphate buffered saline, pH 7.2. Eighteen days after inoculation the mice began to show a paresis of the posterior limbs. No other symptoms were noticeable. A creeping paralysis over the course of 4-5 days caused the death of all the mice, and they were shown to be positive for rabies by the fluorescent antibody technique. Hyperimmune antirabies equine serum effectively neutralized the virus in its ability to infect weanling mice. Dilutions of between $2 \times 10^{-1.2}$ and $2 \times 10^{-7.2}$ were made of a first passage mouse brain suspension and equal parts of these and either normal or hyperimmune horse serum were incubated for 1 h at 37° C. Intracranial injections of 0.03 ml. of each dilution were made into weanling All mice inoculated with the suspension plus normal serum died within 14 days of inoculation. Table 1 shows that only three out of ten mice died in the groups receiving either 10-1.2 or 10-2.2 dilutions plus hyperimmune serum. All mice receiving a more dilute brain suspension and hyperimmune serum survived more than 30 days.

Table 1. NEUTRALIZATION OF ISOLATE BY RABIES ANTISERUM Brain suspension + normal horse serum No. of Dilution mice No. injected dea Brain suspension + hyperimmune anti-rables horse serum
No. of
Dilution mice No. of Dilution No. of deaths injected deaths 10-1·2 10-2·2 10-3·2 10-4·2 10-5·2 10-6·2 5 5 5 5 5 5 5 10-11 2100000 10-5.5 10-3.5 10-4.5 10-6.5 65

These results imply that the dog-faced fruit bat, Cynopterus brachyotis, must be considered as a potential reservoir of sylvatic rabies in Thailand. The significance of bats as carriers of sylvatic rabies is enhanced by the report⁸ of transmission of rabies isolates from bats to a variety of animals by the intramuscular route and by the fact that rabies virus can survive for long periods of time in the brown fat tissue of bats.

Photoelectric Technique for estimating Plasma Coagulation Time

THE usual way of determining time of coagulation, which is of diagnostic importance, is to observe clot formation. There has been no report of any way of measuring coagulation time with an accuracy of a few seconds. We report here our observations of the coagulation of human plasma, using a simple, sensitive and reproducible photoelectric device developed in this laboratory to study blood coagulation. The idea originated from a suggestion of Born1.

The details of the instrument are shown in Fig. 1. The position of the pen is set at maximum when a beam of chromatic light (2 mm aperture) is passed through a sample of clear fresh plasma. The clotting of plasma decreases the photoelectric output to the servo-amplifier, causing the pen to fall slowly.

Fig. 2 shows tracings of the time of coagulation using 2.5 ml. of plasma and 0.5 ml. of 0.025 molar calcium chloride. Volumes as small as 0.5 ml., however, can also The expanded recordings made with increasing sensitivities show that the time required for the voltage

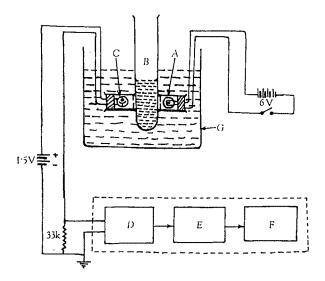

Fig. 1. Diagram of our apparatus. A, Incandescent lamp; B, plasma container; C, photoconductive cell; D, amplifier; E, servo mechanism (SE 21 Gilson Medical Electronics); F, chart drive; and G, thermostat water bath controlled at 37° C.

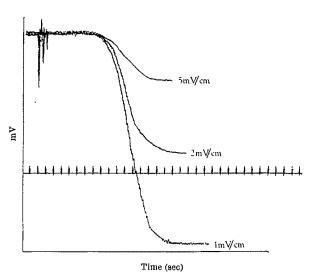

Fig. 2. Decrease in voltage drop as a function of time. Each marking corresponds to 12 sec.

to decrease to a steady minimum value is always 30 sec. Plasmas from different donors, however, show variations in this time. The disturbance of the pen serves as a reference for the time of calcium chloride addition.

The results show that accurate, consistent and reproducible values for the coagulation time can be obtained by using a photoelectric technique. It means that kinetic studies of coagulation can also be carried out.

We thank Professor R. K. Mishra and Dr A. K. Saraya for their encouragement.

Reliability of Predictions of the Contamination of Milk with Fission Products in the United Kingdom

It has been shown¹ that in the United Kingdom a satisfactory guide to the contamination of the average mixed diet with strontium-90 and caesium-137 from nuclear weapons tests is provided by measurements of these nuclides in milk. This is so both for individual years when the rate of fallout is high, and also for the total dietary intake integrated over many years.

The following equation has been found² to give a satis-

The following equation has been found to give a satisfactory relationship between the annual average levels of contamination of milk with both nuclides and the deposition of fallout during the period 1958-64

$$C = p_r F_r + p_l F_l + p_d F_d$$

where C is the annual mean ratio of strontium-90 to calcium (pc./g) or concentration of caesium-137 (pc./l.) in milk; F_r is the annual deposit (mc./km²/yr); F_l is the deposit in the second half of the previous year (mc./km²); F_d is the cumulative deposit (mc./km²); and p_r , p_l , p_d are described as the "rate", "lag-rate" and "soil" proportionality factors, respectively.

The following values of the proportionality factors in this equation were derived

	Strontium-90	Caesium-137
Rate factor (pr)	0.70	3.00
Lag-rate factor (pi)	1.13	6-00
Soil factor (na)	0.11	0.03

Unlike the other factors, which were calculated from survey data by least square analyses, the "soil" factor for caesium-137 was deduced from experimental results because it was too small to be estimated adequately from the survey data.

Table 1. COMPARISON OF CALCULATED AND OBSERVED QUANTITIES OF STRONTIUM-90 IN UNITED KINGDOM MILK, 1968-66

Deposition of strontium-90* (mc./km²)		Strontium-90 in milk (pc. **Sr/g Ca)				
Year	January to June	July to December	Total	Calcu- lated		Calculated % Observed
1958	2.9	2·4	5·3	6.9	7·2	97
1959	6.0	1·7	7·7	10.5	9·8	107

The proportionality factors used were based on data up to the end of 1964 only.

Tables 1 and 2 show that for both nuclides the calculated and observed levels agree closely for each of the years for which data were used in the calculation. It is now possible to test these equations more fully by applying them to the results for the two subsequent years, 1965 and 1966. As in the previous report, the country-wide mean deposition was calculated from the survey results of the Atomic Energy Authority (ref. 3 and personal communica-

¹ Born, G. V. R., Nature, 194, 927 (1962).

tion from R. S. Cambray) and information on rainfall provided by the Meteorological Office.

Table 1 shows that for strontium-90 the agreement between predicted and observed values continued to be close in 1965 and 1966. If new proportionality factors are calculated from the data for the whole period p_d remains unchanged, while p_r and p_l increase by 1 per cent and 7 per cent, respectively. The proportion of the total strontium-90 in milk attributable to uptake from the soil is 43 per cent in 1965 and 63 per cent in 1966, as compared with about 20–25 per cent in years of high deposition². These figures are comparable with those when the rate of deposition was previously declining in 1960 and 1961.

For 1965 and 1966 the equation underestimates levels of caesium-137 in milk by 20 per cent (Table 2). Although the agreement is adequate for practical purposes, it is of interest to recalculate proportionality factors on the basis of the fuller data. The revised factors are: p_r , 2·5; p_l , 6·0; p_d , 0·16. The chief change is in p_d , which is five times that estimated previously from the result of a limited number of experiments. Its value, however, remains so small that it fails to attain statistical significance. Uncertainties regarding this component are not surprising in view of the complex processes which affect the uptake of caesium from the soil⁴; results for a considerably longer period must be assembled before a soil factor for caesium-137 can be derived with confidence.

It is interesting that the more recent data confirm the conclusion previously advanced, on the joint basis of survey results and information on agricultural conditions, that in the United Kingdom the contamination of milk with both nuclides is influenced to an appreciable extent by the rate of fallout in the preceding year.

Although the present method seems to provide a reasonable basis for gauging the extent to which milk will be contaminated as a result of a postulated pattern of fallout, the procedure is approximate only. It has been previously explained. That the processes which control the transfer of strontium-90 to milk are much more complex than the equation implies; the periods to which the rate and lag-rate factors relate are arbitrary and slow changes in the soil factor are to be expected with time. During extended periods slow losses of both nuclides will occur from the root zone; the cumulative deposit in the soil will decrease for this reason as well as by radioactive decay. Present information provides no basis for eliminating these defects.

I thank Dr R. Scott Russell for encouragement and advice.

Accumulation of Glycine in the Fat Body of the Silkworm, Bombyx mori L.

Investigations of intestinal transport of amino-acids in the locust^{1,2} and silkworm^{3,4} have shown no evidence for active accumulation in a transport from the insect gut of amino-acids. When glycine-2-¹⁴C was administered in vivo to fifth instar larvae of the silkworm, 96 per cent

of the radioactivity was incorporated into various tissues within 1 h whereas in vitro only 19 per cent of the activity was transported by the mid-gut of silkworm (unpublished work). These results suggested that continued absorption of glycine by the intestine could be aided by a facilitated diffusion mechanism in which amino-acids are rapidly removed from the site of absorption either by accumulation into other tissues or by degradation. Although the insect fat body has been assigned both accumulatory and dissimilatory roles, the mechanism of accumulation of amino-acids has not been investigated. Our present experiments show that the silkworm fat body possesses an efficient mechanism for accumulating glycine and that both the accumulation and the release of glycine are metabolically controlled.

Table 1. VARIATION OF UPTAKE OF GLYCINE WITH AGE IN THE SILKWORM FAT BODY

Age of silkworm	Percentage absorption for 50 mg fat body with S.E.	P	External concentration ratio
Middle fifth instar larvae	* (a) 24.31 ± 1.87		$\frac{2.36}{1.17}$
Just before spinning stage Mid-pupal stage	(b) 9.37 ± 0.12 5.29 ± 0.67 Nil	< 0.01	0.67

* Larvae from a different batch.

The uptake of glycine was studied by suspending 50 mg of fat body in 0.5 ml. of Ringer solution containing 5 μ l. of glycine-2-14C (specific activity, 0·1 mc./9·8 mg dissolved in 2 ml.) and 7·5 mg of carrier glycine (200 mmoles/l. Ringer solution). The mixture was shaken occasionally and, after the specified time, the fat body was removed from the medium by rapid filtration through glass wool and suitable samples of the medium and alcohol extracts of fat body were plated on planchets. Radioactivity was measured with a Geiger-Müller counter (end-window type). The fat body rapidly took up glycine. Within 6 min the total concentration for the total water of the fat body tissue was found to be between 2 and 3 (Table 1). This fast uptake was maintained up to a glycine concentration of 3 moles/l. (the maximum used in the experiment). Addition of ATP (1 µmole/ml. of incubation medium) had no effect on the absorption of glycine. The time course of the uptake is shown in Fig. 1.

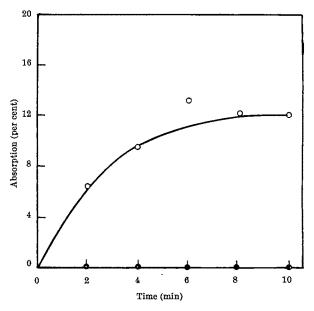

Fig. 1. Time course of uptake of glycine by the fat body of the silk-worm. O, Control; •, cyanide.

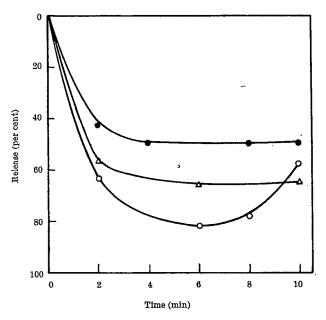

Fig. 2. Time course of the release of glycine from the fat body of the silkworm. O, Control; •, cyanide; A, DNP.

Experiments designed to study the effect of the inhibitors 2,4-dinitrophenol and cyanide have further emphasized the remarkably rapid uptake of glycine. considerable inhibition of uptake was observed with cyanide and to a lesser extent with DNP when the fat body was pre-incubated with the inhibitors (10^{-3} molar) in Ringer solution and used subsequently for absorbing glycine from a medium containing both the labelled substrate and the inhibitor. On the other hand, direct incubation of the fat body with the substrate and inhibitor showed no inhibition of uptake. The rate of uptake of glycine obviously far exceeds the rate of inhibition of the transfer mechanism.

The kinetics of the release of glycine from fat body are shown in Fig. 2. Equilibrium was reached within 10 min and the release was partially inhibited by cyanide (10-3 molar) and DNP (10⁻³ molar). On prolonged incubation there was a reincorporation of the released glycine into the fat body and both DNP and cyanide inhibited this reincorporation.

Fat body is also the most important site of synthesis of proteins and other reactions of amino-acids such as transamination, oxidation and decarboxylation, and so it was necessary to determine the metabolic fate of absorbed glycine. The fat body was fractionated after 30 min of incubation with labelled glycine. More than 90 per cent of the activity was recovered in the alcohol extract and this in turn could be accounted for as glycine. Paper chromatography of the extract showed mainly glycine and a trace of serine. During this period none of the labelled carbon was recovered in the respired carbon dioxide by manometric studies.

The well defined active uptake observed with the fat body tissues suggests that absorption is connected with an organized tissue structure. The dependence of the uptake on the discrete fat body structure is demonstrated by the disappearance of the ability to accumulate during the pupal stage (Table 1). Comparison between middle fifth instar larvae and spinning larvae shows a statistically significant reduction in uptake even at the early spinning stage. These observations are in agreement with electron microscopy studies of the fat body in Philosamia cynthia ricini (L.)^{7,8} during different stages of growth. These revealed the typical double-layered plasma membrane for the fat body cell during the fifth instar and its partial disintegration during the spinning stage. The membrane was not visible in the fat body cells of the pupae.

We thank Professor J. V. Bhat for his keen interest in the work.

Role of Host Plant in Production of Winged Forms by a Green Strain of Pea Aphid Acyrthosiphon pisum Harris

THE importance of tactile contacts between aphids, or the effet de groupe as first described by Bonnemaison1, has been demonstrated in several species of aphids. Lees2 has reviewed work in this field, and has evaluated the claims of those who have invoked "nutrition" as the important factor in the production of these forms, rather than any crowding factor. He concluded: "Unequivocal evidence that starvation or malnutrition, or specific changes in the quality of the plant sap, can cause isolated aphids to become alatae or alata-producers is still lack-

The present work on Acyrthosiphon pisum has shown that, while there is certainly a response to crowding in adult apterae in that some of them produce some alate daughters immediately after the treatment, it is possible to induce aphids reared from first instar in isolation on seedlings to produce many more alate progeny simply by providing them, when adult, with a different food source. In the experiments described here, all aphids have been reared on broad bean (Vicia faba) seedlings (0.5-4 in. high). Only after producing a control "0" batch of larvae on the seedlings were they subjected to any of the treatments described here.

Crowding aphids off the host plant for 24 h in an empty glass tube, at a density of ten/tube, can provide sufficient stimulus for at least some species to produce winged offspring³. This treatment was given to adult apterae of Acyrthosiphon pisum, and a response developed when they were returned to seedlings to deposit young. In Table 1, batch 1 comprises the larvae produced by the mothers of a given experiment in the first 24 h after any particular treatment. Each succeeding batch covers a 2 day period of larviposition. The numbers of alatae produced by the mothers in any batch have been pooled and expressed as a percentage of the total number of larvae in that batch. When the mothers were feeding on seedlings an average of 31 per cent of the larvae born in the first batch after crowding became alatae (Table 1A). Starvation was not the factor inducing the mothers to become alata-producers because control insects which were starved in identical tubes for 24 h, in isolation, produced no alatae at all.

Three experiments were designed to show whether or not the condition of the host plant could influence the number of alatae produced by adult apterae. The results of these experiments are given in Table 1 (B-D). In the first experiment, the aphids were reared as described here and were directly transferred, without previous crowding, to small leaf cages on mature fully expanded green leaves

of 12 in. high bean plants. Their larvae were then removed in batches and were reared on seedlings until the fourth instar, when they were examined for the presence or absence of wing pads. Previous work had shown that larvae of this species are determined as alatae or apterae before birth, any environmental factor such as diet or crowding having no influence after birth. It had also been shown that in such cages contacts between the larvae and the mother do not induce the latter to produce alatae. Hence, any response by the mother, as reflected in the form of her offspring, could only have been caused by the different type of nutrition she was receiving during

Table 1B shows that within 72 h of feeding on the mature leaves, that is, by the end of the second batch, some mothers had started to produce alate daughters. The percentage of alatae was much greater in the third batch, and still greater in the fourth. Indeed, in the latter case the proportion of alate progeny exceeded the values obtained when aphids were crowded and returned to seedlings to reproduce (treatment A). Controls maintained in isolation on seedlings for their entire lives produced no alatae.

(i) Returned to seedlings after 4 days.

(ii) Returned to seedlings after 6 days. Controls

D

The second experiment (C) involved both crowding and host plant factors and can be compared with the initial crowding experiment (Table 1.4). Here the aphids were crowded ten/tube for 24 h, but, instead of being returned to seedlings to reproduce, they were isolated in cages on mature bean leaves, the larvae being removed and reared in the usual way. The effect of the new host plant on these aphids was most marked. The percentage of alatae in the first batch of larvae was more than twice as great as when the aphids were fed on seedlings after crowding, and 100 per cent of the mothers became alataproducers rather than 77 per cent. Furthermore, the aphids continued to produce large numbers of alatae throughout their reproductive lives.

The last experiment (D) was similar to the previous one (C) except that the aphids were returned to seedlings after either 4 or 6 days of depositing larvae on the mature leaves. The results show that most of the aphids produced 100 per cent apterae immediately after the transfer. A few produced from one to five alatae in the first batch on the new host, but then reverted to producing apterae only.

Clearly, as Johnson reported for Aphis craccivora, the type of host plant can play a most important direct part in the production of winged virginoparae in at least some species of aphids. Johnson reared the parent apterae of Aphis craccivora on mature leaves as well as allowing them to reproduce on them, but unless he added a crowding stimulus the response was comparatively weak. My experiments on Acyrthosiphon pisum, however, show that a strong response can be obtained when the aphids are provided with mature leaves after parturition has begun, and that this is true even when the aphids have been kept totally isolated.

I thank Dr A. D. Lees for supervising and encouraging this work.

Delayed Damage to Phaseolus vulgaris L. Seeds by Water trapped during Soaking

Damage to Phaseolus vulgaris seeds through soaking is widely recognized. Successive workers1-6 have interpreted their results as indicating that this is more likely to be caused by the leaching of cell constituents than by oxygen shortage. Our evidence, however, which conflicts with none of theirs, indicates that the rate of oxygen supply to the embryo is the basic problem.

Seeds of the cultivar 'Masterpiece' were soaked in tap water and then placed on moist paper in closed boxes at 20° C in the dark. Our results (Fig. 1 and Table 1) show that short periods of soaking can be favourable to germination, but soaking for longer than 4 h has caused progressive damage. This damage is related to the entry into the intercotyledonary cavity of an excess of water which is then prevented from draining away because the cotyledons swell inordinately and are held pressed together at their edges by the testa. In these conditions the germination percentage declines, some of the seedlings which are tardily produced die soon after radicle emergence and the growth of the survivors is restricted. Yet all these manifestations of damage are completely prevented if the trapped water is released by stripping the testae off the The actual damage does not therefore soaked seeds.

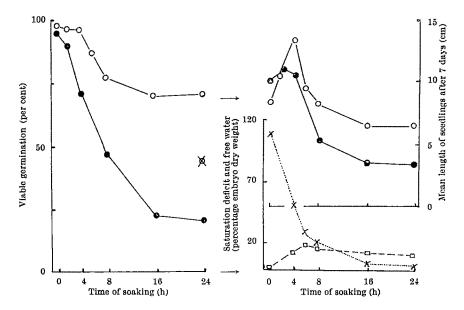

Fig. 1. Effect of soaking in tap water on germination (viable seedlings), seedling growth and water content of seeds of *Phaseolus vulgaris* L., 'Masterpiece': ●, seed lot 1; ○, seed lot 2; ⊕, seed lot 2, with air bubbled through the soaking water; ×, saturation deficit of seed (reaching zero after 24 h soaking); □, free water in the intercotyledonary cavity.

occur while the seeds are under water for 24 h (or indeed 48 h) but after they have been placed in an environment which is normally favourable to germination. This, and the worsened performance when air is bubbled through the soaking water, suggests a detrimental imbalance in the oxygen supply to the embryo (high outside, low inside). Treatment of the seeds with a I per cent solution of hydrogen peroxide before, during or after soaking has virtually the same results as removing the testa, because the solution penetrates into the seeds and gaseous oxygen is released by enzyme action and (Table 1) gradually expels the excess of water from the intact seeds. Consequently, these seeds are capable of germinating immediately on removal from the 1 per cent hydrogen peroxide soak. They will not germinate while in this solution because it is so strong as to be inhibitory but they will germinate while completely submerged in a solution of 0.06 per cent hydrogen peroxide.

Finally, even intact Phaseolus vulgaris seeds soaked in water for 24 h can on removal germinate and grow well if they have, before soaking, imbibed in aerobic conditions about one-third of the water needed for the radicle to emerge. This suggests that germination may be triggered off very early during imbibition, provided sufficient oxygen is available at this stage, and will then proceed unimpaired even though the oxygen supply may be severely restricted later.

This work was carried out while one of us (P. I. O.) was recipient of a grant from the State Scholarships Foundation, Athens. We thank A. Russell for valuable information.

Germination Response to Leaching in Dormant Seed of Trifolium subterraneum L.

DORMANCY in Trifolium subterraneum L. (subterranean clover) has been reviewed by Morley¹. Dormancy in imbibed seed is usually high at harvest maturity but declines with time at rates which differ with strain. High temperatures are inhibitory to germination, and the younger the seed the lower is the inhibiting temperature. Ballard^{2,3} has shown that dormancy in new seed is readily overcome by cold treatment and also by subjecting the imbibed seed to an atmosphere enriched with carbon dioxide at temperatures of up to 25°C; above 25°C, carbon dioxide is unable to abolish completely the inhibition of germination at high temperatures. Dormancy may also be relieved by heat treatment of dry seed4, by removal of the seed coats and by other means. presence of an inhibitor in the seed which is soluble in water has in the past been questioned if not discounted.

Some apparent inconsistencies between germination in the laboratory and germination of clover seed in the field following summer rains are being investigated. In the course of these studies, we have observed a marked germination response, in the laboratory, to leaching seed of T. subterraneum with water. The response to leaching has been particularly marked at temperatures above 25°C, at which there has been little or no response to carbon dioxide treatment. Even at 10°C, however. responses to leaching have been obtained in addition to those obtained by treatment with carbon dioxide.

A recent study on new seed (conducted within a few weeks of harvest maturity) included thirteen strains of T. subterraneum representing a wide range of maturities. At 30°C, the following treatments were examined: (a) seed placed on filter paper in Petri dishes; (b) seed placed on filter paper in flat-sided glass bottles sealed with an atmosphere containing 2.5 per cent carbon dioxide; (c) seed placed in a Buchner funnel and leached continuously with de-ionized water at 10-15 ml./h; (d) testae removed from imbibed seed and the embryos placed on filter paper in Petri dishes; and (e) embryos leached as in (c). In treatments (a), (b) and (d), the filter paper was saturated with de-ionized water, and there was a slight excess of free water in each case. Treatments (a), (b) and

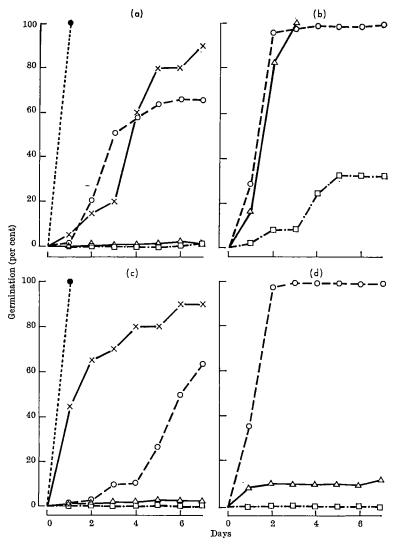

Fig. 1. Effect of seed treatments on germination in two strains of *T. sublerraneum*.

(a) and (b), 'Northam C' at 30° and 20° C, respectively; (c) and (d), 'Burnerang' at 30° and 20° C, respectively.

[], Petri dish; A, 2·5 per cent carbon dioxide; O, leached; x, embryos; , embryos leached.

(c) were also studied at 20° C. In most cases, duplicates of fifty seeds were used in treatments (a), (b) and (c) and twenty embryos in treatments (d) and (e). All treatments were conducted in darkness except for short periods each day when the seeds and embryos were examined in diffuse daylight. Seeds were classed as germinated when the radicles had emerged in the case of intact seed, and when the radicles had elongated in the case of embryos. The percentages of seeds which had germinated were recorded at intervals of 24 h for 7 days. These readings were then summed after the method of Timson?. The final results, recorded as summed germination, $\Sigma 7$, and averaged for the thirteen strains, are presented in Table 1. The time course of germination of two strains, 'Northam C' and 'Burnerang', is shown in Fig. 1.

At 20° C all strains showed some reluctance to germinate in Petri dishes. Twelve strains germinated readily when

Table 1. Effect of a range of seed treatments on the summed germination percentage (Σ 7) of new seed of thirteen strains of T. sublertaneum

Seed treatment	Cumulative germination percentage 20° C 30° C

treated with carbon dioxide, but the remaining strain, 'Burnerang', showed little response. All strains, however, readily germinated when they were leached. At 30° C there was little or no response to treatment with carbon dioxide, but again there was a marked, though incomplete, response to leaching, and more than 50 per cent of the seed of twelve strains germinated within 7 days. The exception at this higher temperature was 'Dinninup', in which only 30 per cent of the seed germinated after leaching for 7 days. removal was partly successful in promoting germination at 30° C, and almost complete germination was obtained within 24 h by leaching the embryos (carbon dioxide was equally effective in promoting germination of the embryos of 'Daliak'—the only strain tested in this way).

In an earlier study, germination tests were conducted over a range of temperatures on seed of four early maturing strains of T. subterraneum which had been stored for 6 months in one case and 3 years in the other. All seeds from both age groups readily germinated in Petri dishes at 10°, 15° and 20° C. Germination rate was slightly enhanced by carbon dioxide treatment and was further slightly accelerated by leaching. At temperatures of 27° C and higher, germination of all seeds was poor in Petri dishes. Carbon dioxide did not promote germination in the younger seed, but gave a marked germination response in the older seed at 27° C and a slight response at 30° C. All seeds germinated rapidly when leached at 27° and 30° C, and even at 35° C appreciable germination was obtained (range, 15 per cent to 90 per cent after 5 days).

The evidence presented here supports the hypothesis that a water-soluble germination inhibitor is involved in the regulation of the germination of seed of T. subterraneum. Moreover, this inhibitor seems to be located partially, if not exclusively, in the embryo. We also have evid-

ence, based on Avena coleoptile section tests, for the presence of both inhibitory and promoting substances in the seed of T. subterraneum. Germination may therefore depend on promoting as well as inhibitory substances, as claimed in other plant species8,9. The possibility that the leaching response may be connected with moisture tension effects or alteration to gas exchange cannot be ignored. The available evidence suggests, however, that these alternatives are unlikely.

Manganese Toxicity in Celery

NECROTIC lesions on the leaflets and petioles of celery, Apium graveolens L. (variety Latham's self-blanching), were observed in a crop grown on a reclaimed peat soil in West Cork. I have shown that these symptoms in celery, which have not previously been reported, were caused by toxic concentrations of manganese in the plant.

The celery was grown on a deep acid peat soil in the Raheen Series¹, which was formed in a low lying area where peat development was associated with poor drainage conditions. The peat was reclaimed in 1964 when it was drained and sea sand equivalent in neutralizing value to 2.5 tons of ground limestone/acre was applied. Oats were sown but failed. The field was fallowed in 1965. In February 1966 sea sand equivalent to 5 tons of ground limestone/acre was applied and subsequently a crop of celery (approximately 1 acre) was produced by the usual horticultural procedures.

In September, samples of (a) healthy, (b) slightly affected, (c) badly affected and (d) very badly affected plants were taken. Each sample was split into four parts, mature and young leaflets and mature and young petioles. Soil samples were taken from around the roots of the four plant samples. Plant and soil samples were analysed by the methods used in the Soil Laboratory, Johnstown Castle².

Table 1. CONCENTRATIONS OF MANGANESE AND ALUMINIUM IN MATURE AND YOUNG LEAFLETS AND PETIOLES OF CELERY (P.P.M. ON DRY MATTER BASIS)

	· Part of plant							
Extent to which	Mature				-	Young		
plants affected	Leafl	Leaflets Petioles		Leaf	Leaflets		Petioles	
-	Mn	Αl	Mn	Al	$\mathbf{M}\mathbf{n}$	Al	Mn	Al
Not affected (healthy)	245	102	70	58	138	66	60	30
Slightly affected	3,300	114	700	96	360	82	250	40
Badly affected	5,423	114	1,167	58	787	122	355	30
Very badly affected	10,270	170	2,635	102	1,795	152	633	ND
ND Not determine	A.		,					

The symptoms, which appeared mostly on the mature parts of the plant, occurred as brown necrotic lesions (approximately 0.25 in. in diameter) on the leaflets and as sunken shiny grey black lesions in the pith between the vascular bundles and as irregularly shaped lesions on the abaxial and adaxial surfaces of the petiole and petiolule, respectively (Figs. 1 and 2). The plants produced new heart leaves and retained an upright habit regardless of the degree to which they were affected.

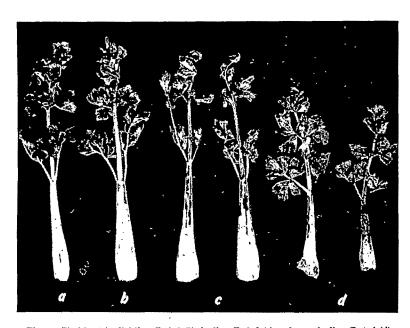

Fig. 1. Healthy (a), slightly affected (b), badly affected (c) and very badly affected (d) leaves showing lesions on leaflets and on abaxial and adaxial surfaces of the petiolules and petioles.

Fig. 2. Irregularly shaped lesions on adaxial surface of petiole and petiolule.

Healthy plants were very well developed and it was expected that a high yield would be obtained in the 70 to 80 per cent of the crop not affected.

Slightly affected plants were retarded in growth and brown necrotic lesions occurred apparently randomly on the leaflets. Lesions occurred in the pith between the vascular bundles on the adaxial surface of the petiolule and the upper part of the petiole (Fig. 1b). Small irregularly shaped lesions also occurred on the edge of the petiolule.

Badly affected plants were considerably retarded in growth. All the mature leaflets were affected; the brown necrotic lesions were more numerous and the leaflets tended to be chlorotic. The lesions occurred most fre-

quently along the edge and veins of the leaflets. In these plants, more intervenal lesions occurred on the abaxial surface of the petiole and petiolule. Irregularly shaped lesions also occurred on the adaxial surface of the petiole and petiolule.

Very badly affected plants were stunted. The lesions on the leaflets were very numerous, tended to coalesce and cover the whole leaflet except for a small area around the junction with the petiolule. The lesions on the petiole and petiolule were also very numerous and in extremely bad cases tended to coalesce to form large necrotic areas on the abaxial surfaces (Fig. 1d). Large irregularly shaped lesions also occurred on the adaxial surface of the petiole and petiolule (Figs. 1d and 2).

The concentrations of manganese in the affected leaflets and petioles were high and varied significantly with the extent to which the plants were affected (Table 1).

The manganese concentration in the leaflets of the very badly affected plants was a hundred times greater than expected. High concentrations of manganese had also been accumulated in the new leaflets and petioles in which, however, no symptoms had developed. Concentrations of

aluminium were very slightly higher in the affected plants, whereas boron and copper did not vary at

In October, variation of pH was determined in soil profiles taken from various parts of the field. In the areas in which the plants were very badly affected, field investigation showed that pH was only satisfactory in the top two to three inches of soil. Below this the peat was very acid (pH 3.9). In the part of the crop in which the plants were healthy and where a good yield was expected. sea sand had been well mixed with the peat. Here the pH in the surface 6-8 in. was satisfactory and the peat below 8 in. was very acid. It was evident that the extent to which plants were affected was correlated with the depth to which sea sand had been incorporated into the peat and therefore with the depth of peat with a suitable pH. Where this was 6-8 in. deep, the rooting medium was satisfactory for maximum plant growth. Where this was only 2-4 in. deep, roots tended to extend from the high pH surface zone into the very acid zone beneath, from which considerable quantities of manganese were apparently absorbed by the plant.

Hewitt has shown that celery is much more susceptible to aluminium than to manganese and that celery crop failure caused by acidic soil conditions usually shows the symptoms associated with aluminium toxicity4. The high concentrations of manganese in the plant and the development of the symptoms described were caused by the absorption of manganese from the acid soil beneath the plant where the sea sand had not been sufficiently incorporated into the peat.

The reason why so much manganese and so little aluminium were absorbed has not been determined. Conroy and Ryan have shown that, although the concentrations of manganese in the native rocks of the West Cork area are not high, sufficient quantities exist to provide sizable accumulations in times. They have shown that high concentrations of manganese occurred in the alluvial soils of the Manch and Ilen series1. It is probable therefore that the high concentrations of manganese have accumulated in the peat, and manganese toxicity in celery has occurred where inadequate mixing of lime with the peat soil has not decreased the availability of manganese in the root zone of the plant.

Fixation of Nitrogen by Bitterbrush (Purshia tridentata (Pursh) D.C.)

THE frequency and importance of nodulated nonleguminous plants are becoming more widely recognized. Allen and Allen¹ have presented a summary of nonleguminous symbiosis in both the gymnosperms and angiosperms and emphasized analogies with the legume-Several workers2-4 have used rhizobia symbiosis. nitrogen-15 to demonstrate that fixation of atmospheric nitrogen does occur in the nodules of many non-leguminous plants.

In 1961, Wagle and Vlamis⁵ reported nodules on the roots of bitterbrush (Purshia tridentata), a member of the family Rosaceae, and presented evidence which suggested that nitrogen fixation occurs in the nodules. We have used nitrogen-15 to study nitrogen fixation by species of non-leguminous plants, including bitterbrush.

Bitterbrush seeds collected in central Oregon were soaked in 10 per cent thiourea for 5 min to enhance germination. The seeds were sown in a sandy soil with a high natural nodulation potential, in 1 pint polyethylene containers, on January 19, 1967. After germination and establishment each pot was thinned to six seedlings. Plants were grown in a greenhouse and the sunlight was augmented by banks of alternating warm-white and daylight fluorescent lamps suspended about 75 cm above the pots to give a day length of 16 h. Day temperature was 21° C and night temperature was 16° C. Plants were watered to maintain moisture slightly below field capacity. After 4 months the seedlings were gathered. Another group of seedlings was grown for a period of 2 months in a growth room with a day length of 16 h at approximately 2,000 ft.-candles at a day temperature of 27° C and night temperature of 21° C. After the seedlings had been removed from the pots, soil was washed from the roots. The nodules were then excised and approximately 0.3-0.5 g of nodule mass was placed in 20 ml. gas-tight serum bottles for exposure to nitrogen-15.

The nodules were exposed to nitrogen-15 within 10 min of excision for a period of 24 h at 20° C in the dark. The atmosphere in the serum bottle was enriched by reducing the pressure within the bottle by removing a known volume of air with a syringe. The pressure was restored to near atmospheric by injecting a calculated amount of nitrogen-15 at the appropriate pressure. The atmosphere in the serum bottle was calculated to contain 14 atm. per cent nitrogen-15. Gas analysis indicated, however, that the atmosphere ranged from 9 to 12 atm. per cent.

After exposure the nodules were removed from the serum bottles and prepared for analysis for nitrogen-15 by mass spectrometry which was carried out in the laboratory of Dr F. E. Broadbent, University of California, Davis.

Virtanen et al.2, who were among the first to use isotopic nitrogen in fixation studies, considered 0.015 atm. per cent of excess nitrogen-15 indicative of positive fixation. We used 0.02 per cent as positive evidence in our studies and the results are given in Table 1. Although there is considerable variation among the samples, they all have an excess of nitrogen above 0.02 atm. per cent. The variation may be due to differences in plant vigour. The nodules in sample 2 came from a vigorously growing 2-month-old seedling. Work in our laboratory with Ceanothus velutinus Dougl. indicates that there is considerable difference in the rate of fixation between nodules from actively growing and dormant plants.

Table 1. ATM. PER CENT EXCESS NITROGEN-15 CONTENTS OF BITTERBRUSH NODULES EXPOSED TO GASEOUS NITROGEN-15

Sample No.	Approximate fresh weight of nodule sample (mg)	Atm. % excess 15 N
1	330	0.075
$\bar{2}$	330	0.379
2 3	300	0.120
4	500	0.155
5	500	0.051

The nodules on bitterbrush have the same coralloid morphology and white colour as those of Ceanothus, and a Streptomyces species has been isolated from bitterbrush nodules which has characteristics similar to the Streptomyces species isolated from Ceanothus velutinus nodules. That this organism is the endophyte still remains to be confirmed by pure culture inoculation and nodulation.

Bitterbrush is widely distributed throughout the ponderosa pine (Pinus ponderosa Laws.) forests and open range lands in the western United States. Although much remains to be learned about the nodulation and nitrogen fixation process in bitterbrush, our results imply that it is making a significant contribution to the nitrogen economies of the ecosystems in which it occurs.

We thank Dr C. M. Gilmour for advice. This work was made possible by a grant from the US National Science Foundation.

MICROBIOLOGY

Intracellular Development of Infectious Bronchitis Virus

Cells infected with infectious bronchitis (IB) virus in tissue cultures of chick or chick embryo kidney have been described as showing shrinkage, vacuolation and detachment from the monolayer1-4. When the immunofluorescent technique was used, the growth of IB virus in chick embryo kidney cells, first in the nucleus and later in the cytoplasma, was described. A study was undertaken to obtain additional information about the location of IB virus, and to determine the type of viral nucleoprotein to assist in classification of the virus6.

Coverslip cultures of chick embryo lung and kidney from 15 and 19 day embryonated eggs, respectively, were stained by coriphosphine, before, and daily for 6 days after, infection with 1,000 EID_{50} of IB virus for each coverslip. The cultures were examined under a Reichert microscope with fluorescent illumination. Infected cell nuclei were seen to become smaller 24 h after infection and the intercellular junctions more distinct (Fig. 1a). Intracytoplasmic granules were clearly visible 48 h after infection with red fluorescence (Fig. 1b) characteristic of

Uninfected chick embryo lung cells stained with coriphosphine 72 h after infection of similar cells with virus (\times c. 500).

The number of normal nuclei and ribonucleoprotein. cells in any one field of the microscope at this time was greatly reduced. By 72 h, the granules had coalesced to become red-fluorescing intracytoplasmic inclusions (Fig. 1c), and the nuclei of infected cells were pyknotic. Few normal cells remained.

Many isolates from what appears to be clinical IB disease have been found in this laboratory not to be pure IB virus, but commonly mixtures of two viruses, most often IB virus and avian adenovirus. Neutralization of the IB component of such a mixture with specific IB antiserum, and the passage of such virus serum complexes in chick embryo kidney tissue culture, were found to be the best way of recovering the adenovirus component from mixtures of IB virus and adenovirus, and of making a preliminary identification of a contaminating desoxyribonucleoprotein virus, as cells infected with adenovirus show bright green fluorescence in their nuclei.

In four out of 150 separate chick embryo lung or kidney tissue culture preparations from embryonated eggs from the same IB-free flock extensive cytoplasmic vacuolation appeared to develop spontaneously in uninoculated monolayers. Repeated attempts to reproduce such vacuolation by passaging collections of affected monolayers in normal cultures proved unsuccessful. Inoculation of material into the allantoic cavity of 10 day embryonated eggs and onto the chorio-allantoic membranes of 8 day embryonated eggs failed to demonstrate the presence of an infectious agent.

It appears that vacuolation of the cytoplasm of monolayers infected with IB virus is not necessarily related to the presence of an infectious agent as previously suggested1,2,4. Furthermore, no indication was obtained that

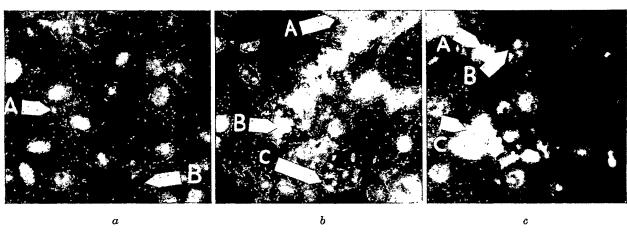

Fig. 1. Chick embryo lung cells, infected with 1,000 BID_{50} Massachusetts strain IB virus and stained with coriphosphine (\times c. 500). a, 24 h after infection; A and B show granular appearance of cytoplasm. b, 48 h after infection; A, B and C show the intracytoplasmic granules. c, 72 h after infection; A shows a pyknotic infected nucleus, B and C point out the intracytoplasmic granules coalesced to become inclusions.

virus may develop initially in the nucleus, but it was noticed that the shrunken size of the nuclei of infected cells was accompanied by brighter fluorescence when stained with coriphosphine, although this was taken to be non-specific.

On the basis of criteria previously proposed, it seems that IB virus is a ribonucleoprotein type virus, developing as intracytoplasmic granules that coalesce to form inclusions.

BIOCHEMISTRY

Effects of Antibiotics on Protein Synthesis in Muscle and Implications with regard to the Action of Insulin

Many compounds are specific inhibitors of protein synthesis and the mechanism of their action has been much investigated. Not all compounds which inhibit protein synthesis in micro-organisms do so in ribosomal systems of mammalian origin, for example, chloramphenicol¹⁻³. In yeasts an interesting dichotomy has been described between materials inhibiting mitochondrial but not ribosomal systems, for example, tetracycline and macrolides, and vice versa, for example, cycloheximide4.

The incorporation of amino-acids into protein by isolated rat diaphragm has been used extensively for studies of the mechanism of the action of insulin and has the advantage of representing an isolated intact cell preparation in which to study protein synthesis. The isolation of polysomal aggregates from muscle^{6,7} reveals the basis of the tissue's capacity to synthesize protein. Because the system is probably less active than that of liver^{8,9}, and isolated muscle mitochondria possess considerable incorporating activity^{10,11}, the extent to which the in-corporating capacity of the intact tissue is microsomal or mitochondrial is not clearly established.

Investigation of the inhibitory influence of various antibiotics and other materials on protein synthesis in isolated rat diaphragm muscle is of value both as a comparison of animal versus microbial systems and as an indication of the location in vivo of the synthetic activity. It is also useful to correlate the extent to which materials much used to regulate the metabolism of isolated organelles will affect intact cells and their response to hormones.

The procedure for the preparation and incubation of diaphragm and for the assessment of incorporation of amino-acids into protein and their accumulation in the tissue has been described before 12-14. The agents used were added directly to the incubation medium which contained no added glucose unless figures for glucose uptake are given.

Table 1. Effect of various antibiotics on the incorporation of ¹⁴C-GLYOINE INTO THE PROTEIN OF ISOLATED RAT DIAPHRAGM

Additions to the medium	Insulin present (0·1 U/m!.)	Radioactivity incorporated into protein (c.p.m./mg protein)
No addition	-	58.7 + 5.8
Cycloheximide $(1 \mu g/ml.)$	_	$12 \cdot 2 \pm 1 \cdot 2$
Cycloheximide (10 µg/ml.)	_	6.0 ± 0.70
Cycloheximide (100 μ g/ml.)		1.8 ± 0.11
No addition		42.1 ± 2.7
Tetracycline (100 µg/ml.)		37.1 ± 2.9
No addition	+	88.4 + 3.5
Tetracycline (5 µg/ml.)	÷	88.7 ± 7.3
No addition	-	42.9 ± 1.7
Erythromycin (100 μ g/ml.)		43.0 ± 2.3
No addition	_	52.5 ± 3.1
Chloramphenicol (100 μ g/ml.)	****	53·3 ± 2·9
No addition	+	91.0 ± 4.0
Chloramphenicol (100 μ g/ml.)	+	90.8 ± 5.4

Each figure is the mean \pm standard error of the mean of six observations. Incubation was for 2 h and the ¹⁴C-glycine (specific gravity about 5 mc./mmole) was added undiluted at about 0·1 μ c./ml.

Incorporation of amino-acids into protein by diaphragm is inhibited by puromycin¹⁶, actinomycin^{16,17}, proflavin¹³ and by numerous metabolic inhibitors¹⁸. Incorporation is also inhibited by cycloheximide (Table 1) which in yeasts is an inhibitor of cytoplasmic ribosomal as opposed to mitochondrial synthesis4. It is not affected by the presence of tetracycline, erythromycin or chloramphenicol the inhibitory influence of which on mitochondrial protein synthesis is established^{11,19}, either in the absence of insulin or when incorporation is subject to insulin stimulation (Table 1). These figures indicate that most incorporation observed with isolated diaphragm muscle results from the activity of extramitochondrial synthesis, and the figure of 20 per cent for mitochondrial activity suggested by Florinis must be an upper estimate. Muscle, as opposed to yeast in a growth phase, is obviously unlikely to form mitochondrial materials very fast. Although mammalian protein synthesizing systems are for the most part resistant to inhibition by chloramphenical, inhibitory influences that have been reported mostly represent situations in which there is introduction of new messenger-RNA²⁰⁻²³. Chloramphenical shows no toxic effect on incorporation even in the presence of insulin. This reinforces a point previously made with actinomycin²⁴ that the action of insulin in muscle on the numerous responsive parameters is not brought about through stimulation of nucleic acid syn-

Table 2. Effect of insulin on the uptake of glucose and of aminoisobutyrate by isolated rat diaphragm after incubation with puromyoin or cycloheximide

Antibiotic added	Insulin added	Uptake of glucose (mg/g wet weight/h)	$ \begin{pmatrix} \text{Aminoisobutyrate accumulated} \\ \text{(Ratio } \frac{\text{c.p.m./ml. tissue water}}{\text{c.p.m./ml. incubation medium}} \end{pmatrix} $
None Cycloheximide	-		$\begin{array}{c} 1.55 \pm 0.094 \\ 1.24 \pm 0.064 \end{array} \} P < 0.05$
Cycloheximide Cycloheximide	- +	$\begin{array}{l} 2.35 \pm 0.32 \\ 3.62 \pm 0.13 \end{array} \} P < 0.01$	
Puromycin Puromycin	 +	$2.39 \pm 0.10 \atop 4.00 \pm 0.33$ $P < 0.001$	$1.33 \pm 0.047 \\ 1.79 \pm 0.083$ $P < 0.001$

Each figure is the mean \pm standard error of mean of six observations. The concentration of puromycin or cycloheximide added was 100 μ g/ml. and in each case, the tissue was pre-incubated for 3 h with or without the inhibitor before the test incubation of 1 h,

Other materials used on occasion as inhibitors of protein synthesis include amino-acid and nucleotide analogues. Neither azauridine (1 mmolar), 5-fluorouracil (10 μmolar), DL-norleucine (20 mmolar) nor DL-ethionine (20 mmolar) have any appreciable inhibitory influence on incorporation by diaphragm even during incubation periods as long as 6 h. It could be argued that the materials do not readily penetrate the tissue—but the uptake of amino-acids is well established, the incorporation of nucleotides readily observable and the rapidity with which molecules as large as puromycin, actinomycin and cycloheximide exert their influence is impressive. Uptake of chloramphenicol by reticulocytes has recently been studied23.

Table 3. Effect of insulin in the presence of cycloheximide on the accumulation and incorporation into protein of ¹⁴G-glycine by isolated rat diaphragm

Insulin added	(Ratio c.p.m./ml. tissue water c.p.m./ml. medium)	Radioactivity incorporated into protein (c.p.m./mg protein)
-	$2.04 \pm 0.18 \\ 2.95 \pm 0.21$ $P = 0.01$	${16.5 \pm 0.70 \atop 22.3 \pm 1.10} P = 0.001$

Each figure is the mean \pm standard error of mean of six observations. The tissue was pre-incubated for 30 min in the presence of 2 μ g/ml. of cyclohexlmide before addition of the ¹⁴C-glycine (0·2 μ l./ml.).

Table 4. Effect of administration of cycloheximide *in vivo* on the capacity of the subsequently isolated diaphragm muscle to incorporate ¹⁴C-Glycine into protein and to respond to insulin

Animals injected with	Isolated diaphragm with insulin	Uptake of glucose (mg/g wet weight/h)	Radioactivity incorporated into protein (c.p.m./mg of protein)
Saline		$3.58 \pm 0.25 \\ 6.38 \pm 0.20$ $P < 0.001$	$\frac{145}{949}$ $\pm \frac{22}{140}$ $P < 0.01$
Saline	+	6.38 ± 0.20 } ~ ~ 0.001	
Cycloheximide		2.89 ± 0.31 6.55 ± 0.17 P < 0.001	21.7 ± 0.92
Cycloheximide	+	6.55 + 0.17	30.4 + 2.90 1 - 0.02

Each figure is the mean \pm standard error of mean of six observations. The cycloheximide (10 mg/150 g of rat²³) was injected intraperitoneally (in saline) 90 min before removal of the diaphragm.

Extensive incubation with puromycin lowers the capacity of muscle to take up amino-acids25, although the effect is not seen in shorter incubations26. suggested that the membrane carrier for amino-acids may be a protein with a rapid rate of turnover. Wool and Cavicchi²⁷ have also provided evidence that puromycin and cycloheximide interfere with the response of a muscle ribosomal system to insulin, and they suggest, by analogy with similar findings with adrenocorticotrophic hormone²⁸, that a primary action of insulin is to promote formation of a labile protein which is responsible for increasing the activity of the polysomes. I have confirmed the findings25 of the inhibitory effect of puromycin and cycloheximide on accumulation of aminoisobutyrate (Table 2). But an effect of insulin to promote aminoisobutyrate accumulation remains observable, albeit on a smaller absolute scale, and promotion of glucose uptake is also seen. A normal percentage increase of incorporation by insulin is observable (Table 3) although it is reduced by pre-incubation with cycloheximide. cycloheximide is administered in vivo before removal of the diaphragm, the tissue again responds to insulin both with respect to glucose uptake and amino-acid incorporation (Table 4). These observations do not support the concept that the primary actions of insulin on muscle, whatever they are, are dependent on proteins with a rapid rate of turnover and renewal. Because cycloheximide is thought to bind to ribosomes, a more mundane interpretation of the results of Wool and Cavicchi²⁷ and possibly those of Garren et al.28 would be that the ribosomal systems isolated after treatment with cycloheximide remain contaminated with the inhibitor and, despite some apparent incorporating capacity, are effectively dead. In these conditions hormonal response is unlikely to be observed. The question remains why cycloheximide in vivo was not found totally to inhibit incorporation by diaphragm. This is probably a technical question of dosage

as can be shown with puromycin¹⁷. A more important question is why ribosomal systems from animals treated with inhibitors exhibit incorporating capacity at all (for example, refs. 29, 30). Without a clearer understanding of the full enzymology of protein synthesis this is difficult to answer.

I thank Mrs K. Parkes for technical assistance and the Medical Research Council for financial support.

Growth Hormone and Carbohydrate Metabolism in vitro

In the recent communication under this title, Bolodia and Young' say that "... no satisfactorily reproducible effect of growth hormone in vitro on carbohydrate metabolism has been described". No grounds are given for rejecting the comprehensive evidence of Ottaway and Bulbrook² for effects on the glucose uptake of rat diaphragm which are practically identical with those now described by Bolodia and Young, nor for the evidence of Bronk and Fisher³ that very small concentrations of bovine growth hormone produce anti-insulin effects on the perfused rat heart. Bronk and Fisher showed that growth hormone reduced glucose uptake and permeability to galactose in the absence of insulin as well as in its presence. It follows that growth hormone produces an effect which offsets the action of insulin but is not acting as an anti-insulin.

Hydrocortisone Induction of Tyrosine Transaminase in Regenerating Rat Liver

THE "minimal deviation" hepatomas—well differentiated rat hepatocellular carcinomas—demonstrate many abnormal enzyme regulatory mechanisms. It has been suggested that these alterations are critical in neoplastic transformation. The corticosteroid induction of the hepatic enzymes tryptophan pyrrolase (TP) and tyrosine transaminase (TT) has been extensively studied in these tumours. Administration of corticosteroid causes a considerable increase in the activities of TP and TT in the normal adult rat liver within 4–5 h (refs. 3 and 4). In hepatomas, however, there is little or no increase in TP activity after administration of corticosteroid, and baseline enzyme activity is usually depressed.

It has been shown that the corticosteroid induction of TP is markedly depressed during the period of DNA synthesis after 70 per cent hepatectomy in the rat^{5,6}. This indicated that during the preparation for cell division this particular enzyme regulatory mechanism was also

altered in a non-neoplastic cell.

In contrast, the corticosteroid induction of TT in several tumour lines was found to be normal and baseline enzyme activity was either normal or increased. We have examined the pattern of steroid induction of TT in the regenerating rat liver after 70 per cent hepatectomy to determine whether the induction was altered during the preparation for mitosis in a non-neoplastic cell.

Male Sprague-Dawley rats weighing approximately 250 g underwent either a 70 per cent hepatectomy? or a sham operation on the morning of each experiment. The rats had been adrenalectomized 5-7 days previously

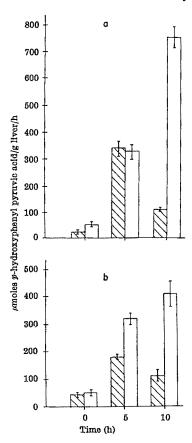

Fig. 1. Tyrosine transaminase activity after hydrocortisone administration a, 2 h, and b, 21 h, after operation. Values on abscissa are hours after injection of steroid. There were five rats in each group and brackets indicate \pm standard error of the mean. Hatched columns, sham operated; white columns, hepatectomized.

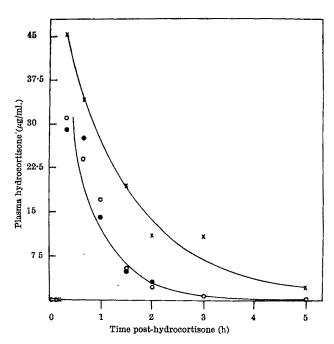

Fig. 2. Disappearance of plasma hydrocortisone after intraperitoneal administration. Each point is average for two rats. ●, Unoperated; O, sham operated; ×, 70 per cent hepatectomized.

and had been maintained on 0.9 per cent saline and lab chow given freely. Hydrocortisone phosphate (5 mg/100 g) was administered intraperitoneally 2 or 21 h after operation. No new DNA synthesis occurs in the early post-operative period after 70 per cent hepatectomy, but at 21 h the synthesis of DNA has achieved a significant rate⁸. The rats were killed 0, 5 and 10 h after administration of hydrocortisone, and TT was assayed by the method of Lin and Knox⁴. Previous experiments had shown that neither prior adrenalectomy nor administration of hydrocortisone appreciably altered the mitotic response after 70 per cent hepatectomy. It had also been shown that neither of these procedures nor sham operation raised hepatic mitotic activity above that of an intact unoperated rat^{5,8}.

Hydrocortisone induction of TT activity in both unoperated and sham operated adrenalectomized rats was similar to that described before, with respect to both the pattern of induction and the degree of peak activity.

At both 2 and 21 h after 70 per cent hepatectomy the kinetics of induction of TT were altered (Fig. 1). Enzyme activity 10 h after injection was significantly greater than at 5 h, contrasting with the return towards baseline values shown by the sham operated rats. After 5 h, the time of expected peak induction, activities were similar in both groups of rats. Basal enzyme values in the 70 per

cent hepatectomized rats were also elevated.

These findings initially suggested that control mechanisms for TT were altered during hepatic regeneration, but not temporally related to DNA synthesis as had been observed for TP. In contrast to TP, TT appeared to be hyperinducible. It has been shown, however, that repeated small doses of hydrocortisone, in contrast to a single large dose, cause a pattern of induction of TT in unoperated rats similar to that seen in the hepatectomized group in this investigation. It seemed possible therefore that removal of 70 per cent of the functional liver might result in an alteration of hydrocortisone metabolism, leading to sustained exposure of the residual liver to circulating steroid. To test this possibility, plasma concentrations of hydrocortisone were determined in 70 per cent hepatectomized and sham operated rats after a single intraperitoneal dose of steroid at the same dose level used in the previous experiment¹¹⁻¹³.

Fig. 2 indicates that plasma clearance of hydrocortisone is markedly slowed in the case of 70 per cent hepatectomy. The residual hepatic parenchyma was therefore exposed to a greater concentration of circulating steroid for a longer period of time than controls; values 3 h after injection were ten times greater than controls.

It should be noted that this phenomenon must be considered when experiments utilizing an agent metabolized by the hepatic parenchyma are performed in partially

hepatectomized rats.

It seems probable that TT is fully inducible in the regenerating rat liver and that the alteration of induction kinetics is caused by a prolonged exposure to steroid rather than a fundamental change in enzyme regulation.

The differences in the hydrocortisone induction of TP and TT during hepatic regeneration may reflect a relationship between their mechanisms of control and the metabolic events accompanying the preparation for cell division. These factors may also be operative in the "minimal deviation" hepatomas.

We thank Dr William D. Drucker and Miss Annamarie L. Verde for determining plasma hydrocortisone. work was supported by grants from the US National Institutes of Health and the American Cancer Society.

Ergosterol Peroxide: a Fungal Artefact

ALTHOUGH the isolation of ergosterol peroxide from the extracts of several different fungi has been reported1-4, the question of its authenticity as a metabolite in these cases does not seem to have been raised. In the present case, the peroxide was found to be present in extracts of sporophores of Piptoporus betulinus or of Daedalea quercina. These extracts, however, had been exposed to daylight for several days and the peroxide could not be detected initially in fresh extracts. Ergosterol (R_F 0.40) and ergosterol peroxide $(R_F \ 0.23)$ were both easily detected by T.L.C. on silica using 1 per cent methanol in chloroform as eluent, characteristic intense blue-black and dark green colours, respectively, being developed after spraying with ceric ammonium nitrate and heating briefly at 100° C. A sample of the peroxide isolated after chromatography on silicic acid was identical in all respects with a synthetic sample.

It can be shown that, in the conversion of ergosterol to its peroxide under a slow stream of oxygen, both light and a photosensitizing substance (for example, eosin⁵) are essential. The crude brown gummy materials extracted with methanol from P. betulinus and D. quercina were each able to act as photosensitizer, and 100 mg or more of either extract allowed complete oxygenation of ergosterol (10 mg) in methanol (10 ml.) under an ordinary 150 watt pearl lamp in 18 h. This photosensitizing property, which was not impaired by boiling the crude extract with acid or base, is one which is exhibited by a wide range of coloured compounds to varying degrees. (The fungal anthraquinones emodin and physcion⁶, for example, were found to have up to 20 per cent of the sensitizing activity of eosin, a minimum of 50 µg allowing complete oxygenation of 10 mg of ergosterol in 18 h.) Hence, as most fungal extracts contain at least small quantities of pigments, isolated ergosterol peroxide may be, in general, an artefact rather than a natural product.

PHYSIOLOGY

Apparent Peroxide in the **Blood of Pregnant Mice**

In previous communications^{1,2}, it was shown that the total apparent peroxide in mice was decreased by an oral contraceptive and increased by pregnancy. The uterus, ovarian fat plus ovaries, mammary tissue and adrenals of pregnant mice each showed a significant increase, but the total amount of increased peroxide in these organs accounted for only about 6 per cent of the whole mouse increase. In a further attempt to locate the peroxide induced by pregnancy, the blood of pregnant mice was examined.

The pregnant albino hairless mice and the peroxide estimations using an anoxic box were as previously described2.3. Ten control and ten pregnant mice, initially 13 weeks old, were used for this experiment, Blood was drawn from the right ventricle of the dead mouse and weighed in a thin walled glass bulb. The glass bulb was macerated with the blood.

For the calculations of peroxide in total blood it was assumed that blood is 10 per cent of the body weight.

Table 1. MICROMOLES OF PEROXIDE IN MOUSE BLOOD

	Mean peroxide	Peroxide/g.
Control	1.52	0.59
Pregnant	5-96 P < 0-01.	1.71
	L < 0.07"	

As shown in Table 1 there was a significant increase of peroxide in the blood of pregnant mice and this accounted for about 73 per cent of that in the whole mouse.

Selective Antagonism of Arsenicals and Antimonials

WE have long been looking for an antagonist of arsenicals and antimonials to decrease selectively their toxic action, without interfering with their therapeutic effectiveness. The dimercaptans behave in the opposite way: for example, 2,3-dimercaptopropanol (BAL), in one-eighth of the dose of 'Arsenoxide' employed, abolishes antitrypanosomal activity, and only multiple doses of toxic arsenic can act as antidote1. Having observed BAL to abolish the activity of penicillin and chloromycetin in spirochaete infections without affecting antistreptococcal activity2, we realized that selective antagonism against particular cells, which could be host cells, is possible. We found that 'Penicillamine' (dimethylcysteine, DMC) which is known to detoxify bivalent heavy metals (mercury, lead) $^{3-5}$ is also a powerful antidote against arsenicals and antimonials, which does not interfere, within a wide range, with their antiparasitic effectiveness in vivo and in vitro.

During the past 6 yr we have investigated the influence of DMC and its analogues on arsenicals and antimonials in vivo and in vitro on schistosomes, leishmania and trypanosomes, as well as in different hosts.

As an antidote against 'Arsenoxide' (Mapharsen), DMC compares favourably with BAL and is less toxic. (Subcutaneous LD_{50} in mice for BAL is 150 mg/kg, for dl-DMC is 450 mg/kg and for d-DMC is 650 mg/kg.) The LD_{95} of 'Arsenoxide' is 50 mg/kg and the compound is detoxified by 20 mg/kg of dl-DMC given twice 30 min before and after the arsenical. As for bivalent metals, d-DMC is a more effective antidote to arsenicals than its optical isomer.

Table 1. Effect of dl-dimethyloysteine on the antitrypanosomal and toxic action of 'arsenoxide' in mice

	Antagonism	50	80×1	12†			0

Without trypanosomes in the blood stream.
 Subdivided into three groups of four mice receiving DMC 2, 1 and 0.5 h before injection of 'Arsenoxide'.

Doses of DMC from 1 to 80 mg/kg, given twice to sixtyseven mice infected with T. equiperdum and treated with 2 mg/kg of 'Arsenoxide', did not inhibit the therapeutic activity of the arsenical, although thirty-nine animals received antagonistic doses (two of 10-80 mg/kg) sufficient to give protection against lethal 'Arsenoxide' intoxication. In tryptose-phosphate broth, 25 µg/ml. of 'Arsenoxide' kills the trypanosomes within 40 to 60 min; addition of 100 µg/ml. of DMC does not modify this activity, which can be slightly delayed by 200 µg/ml. of DMC. To abolish effectiveness, both in vitro and in vivo, very large excesses of DMC are required, which also applies to the anti-bacterial action of mercurials. For example, *L. enriettii* in culture is killed within 24 h by 0·125-0·25 mg/ml. of tartar emetic, an action which is not modified by 5-10 mg/ml. of DMC, but is totally abolished by 25-50 mg/ml., that is, hundred-fold excess, which leaves a vigorous population of parasites even after 10 days.

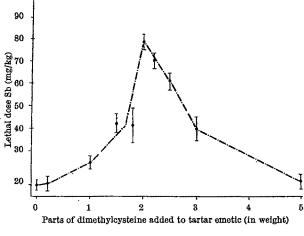

Fig. 1.

The curve of tolerance of antimonials to which increasing amounts (0.25-5.0 parts by weight) of DMC are added is parabolic: maximum detoxification, which in the case of tartar emetic reaches 300 per cent, is followed by additive toxicity (Fig. 1). In these experiments with antimonials, both d- and l-DMC were effective. On the other hand, the clearing effect of 15 mg/kg of tartar emetic on the parasitaemia of mice (T. equiperdum), completely abolished by 30 mg/kg dimercaptosuccinic acid, was not modified by 30 mg/kg of dl-DMC.

It is of theoretical and therapeutic interest that the selective antagonism is limited to specific structures. Cysteine is known, to deactivate as much as it detoxifies, and we found that dimercaptosuccinic acid in doses of 10-30 mg/kg abolishes the antitrypanosomal activity of 10-15 mg/kg of tartar emetic.

This selective antagonism with DMC led us to prepare drugs with increased therapeutic indices. For example, antimony-tris dl-ββ-dimethylcysteine (Sb (DMC₃)), containing 19.5 per cent antimony, has a toxicity: clearing ratio as high as 15 in T. equiperdum infection of mice. This compound can be further detoxified by the addition of 1 mole of DMC without loss of effectiveness. The arsenic substituted dl-DMC derivative of 'Arsenoxide' (3-amino 4-hydroxy-phenarsine di-ββ-dimethylcysteine trichlorhydrate), with a 12.08 per cent arsenic content, toxic to mice in 200 mg/kg doses clears T. equiperdum infection in doses of 2.5-3.0 mg/kg and induces a permanent cure in a dose of 12 mg/kg. The resulting safety margin is considerably greater than that of 'Arsenoxide'.

A preparation (NAP) to which we attribute the structure

complexed with an additional amount of DMC, seemed by its reduced toxicity and high antiparasitic action (S. mansoni, T. equiperdum, T. venezuelensis) to be particularly suitable for chemotherapeutic use, and we have been investigating it since 1964 in the local Anti-bilharzia Center of the Venezuelan Ministry of Health in patients infected with S. mansoni. Ron Pedrique et al. gave a very favourable clinical report on this drug; there were no significant side effects and a high curative rate (80 per cent) in patients treated intramuscularly, during 5

days, with a total dose corresponding to 300 mg of antimonv.

Two fundamentally different processes seem to be involved in this selective antagonism. (a) The antagonist inhibits some, but not all, biochemical effects of the agonist. This is undoubtedly the case for the inactivation of BAL in the antispirochaete action of penicillin, which leaves the antibacterial activity unaffected2. (b) The antagonist enters into a reaction with the agonist forming conjugates with different biological properties, for example, with lower toxicity and high antiparasitic activity, which may apply to DMC.

The overall inhibition of activity obtained with very large excesses of DMC may depend on a different mechanism: donation of sulphydryl groups which reactivate the receptor site of the parasite and/or block directly the effect of the drug on it. The latter mechanism, attributed to the excessive doses of DMC, may be analogous to the mechanism of inhibition of the antiparasitic activity of arsenicals and antimonials by the dimercaptans, BAL and dimercaptosuccinic acid2,9.

Significance of Respiratory Quotients in Toad Bladder and Kidney

THE respiratory quotient is an established guide for deducing the main class of substrate which is completely oxidized by the intact aerobic organism¹. Incomplete oxidation of substrates has, however, been shown to occur in vivo in individual organs, such as kidney2,3 and heart4, and so an interpretation of the respiratory quotient cannot be made for observations of gaseous metabolism in an isolated tissue or a single organ without simultaneous evidence of complete substrate oxidation.

The observations of incomplete substrate oxidation by organs are consistent with the concept that the complete aerobic oxidation of substrates in the whole organism results from sequential or partial substrate oxidations in a series of organs. Thus the respiratory quotient of the organ is determined not only by the substrates used, but also by the degrees to which substrates are oxidized, and used for syntheses, and the intermediary metabolic

pathways involved.

Some recent reports of tissue metabolism in vitro and in vivo have not considered these limitations in the interpretation of the respiratory quotient. For example, Maffly and Coggins have reported that the rate of Δ carbon dioxide production parallels Δ short circuit current in the toad bladder preparation and, from published data on oxygen consumption by the toad bladder, they deduce that the respiratory quotient of this tissue is in the range

of 1.2-1.4. They consider the latter figure to be close to unity and suggest that the energy for the transport of sodium ions is derived from the complete oxidation of endogenous carbohydrate, particularly because the toad bladder has been shown to utilize exogenous glucose avidly.

Maffly and Coggins also suggest that the high respiratory quotient of dog kidney² may be accounted for by conversion of carbohydrate to fat⁶. It is not clear whether they also imply that in dog kidney the energy for sodium transport may be derived from the complete oxidation of glucose. If glucose is taken up by the kidney and converted to fat, the respiratory quotient might indeed be raised; however, the known smallness or absence of glucose uptake⁷⁻⁹ by the dog kidney makes it highly improbable that glucose extracted from renal arterial blood is being used both for sodium transport and for fat production. If glucose is being converted to fat, the energy requirements for sodium transport must be largely derived from the oxidation of other substrates, for sodium transport and fat synthesis are both endergonic processes. Thus while these speculations about the relationship between gaseous and intermediary metabolism and sodium transport in the toad bladder and kidney may have some basis, specific interpretations of the respiratory quotient are questionable in the absence of complete quantitative studies of the metabolism of the endogenous substrates of, and the metabolic pathways in, organs.

Similarly, Nieth and Schollmeyer¹⁰ have reported that the large uptake of non-esterified fatty acid by human kidney is consistent with an observed renal respiratory quotient of 0.7. (It should be noted that if the respiratory quotient is calculated using the data they present the figure is closer to 0.8.) They also calculated that the complete oxidation of the total substrates taken up by the human kidney could be accounted for by the simultaneously measured renal oxygen consumption¹¹. tunately, Nieth and Schollmeyer made no estimate of the renal uptake of glutamine which must have occurred during their observations. Calculations from the uptake of glutamine by human kidney12 indicate that between 15 per cent (normal man) and about 35 per cent (during acidosis) of the estimated renal consumption of oxygen may be accounted for by glutamine oxidation. Calculations made from observations in the dogs indicate that the mean renal uptake of glutamine may account for about 17 per cent (alkalosis) to 35 per cent (acidosis) of the renal consumption of oxygen. Thus if one assumes that uptake and complete oxidation of glutamine were also occurring in the human subjects11, the calculated respiratory quotient would be even higher than 0.8. The addition of glutamine to the substrates taken up by human kidney then makes the observed oxygen consumption grossly insufficient for complete oxidation of the total substrates. Thus it seems that the substrate oxidation in the studies of in vivo human renal metabolism was incomplete, and that the respiratory quotient cannot be used to determine the substrates which are used.

The basis for the respiratory quotient of kidney or toad bladder is not yet clear. In the case of the dog or human kidney, it seems that an important endogenous substrate is non-esterified fatty acid²,¹¹,¹³. Complete oxidation of non-esterified fatty acid should yield a respiratory Complete oxidation quotient of ~0.7, but incomplete oxidation could result in a respiratory quotient of more than unity2, the degree of elevation depending on the relative amounts of fatty acids completely and incompletely oxidized. Furthermore, because the sum of the substrates taken up by the dog3 or human kidney cannot be completely oxidized by the simultaneous oxygen consumption, there must be partial dissimilation of some substrates, for example, nonesterified fatty acid or glutamine, which would be consistent with a high respiratory quotient related perhaps to renal work.

I should also like to emphasize that the bases for the respiratory quotient in mammalian kidney and toad 'bladder or other tissues transporting sodium transcellularly, such as frog skin, may not be alike because the substrates which can be taken up by each of these organs are different (Table 1). The dog kidney in vivo shows a definite substrate specificity in that lactate. pyruvate^{8,14,15}, glutamine, α-ketoglutarate^{15,17} and palmitate13 are avidly taken up from the arterial blood, whereas glucose, glutamate and oleate12 either are not taken up or are utilized at relatively low rates. Maffly and Edel-man¹⁸ have reported that the toad bladder similarly displays a varied but differing hierarchy of affinities for substrates, in that α-ketoglutarate is utilized at a very low rate, while glucose and pyruvate are utilized briskly (Table 1). Such differences in substrate specificities among organs transporting sodium ions may indicate that their patterns of intermediary metabolism are dissimilar. If there are both specific substrates17 and specific exergonic reactions18 coupled to ion transport in each organ, they may not be the same for kidney, toad bladder, frog skin or other sodium-transporting structures.

Table 1. Substrate selectivity and affinity of three tissues which transport sodium transcellularly

	Toad bladder	Dog kidney (in vivo)	Frog skin

Malate	+ 18		+ 23*

A qualitative scale of substrate affinities is used because the data are derived from observations made in widely varied circumstances. Moreover, the methods used for quantification of substrate uptake were different in each study. \pm , Small net utilization or production; 0, no net uptake; +, small net uptake; +, + + +, in the case of the kidney, a large enough net uptake, in some instances, to account for observed or estimated renal consumption of oxygen.

- * Data from Huf based on effect of substrate at 5 mmolar on $\dot{Q}o_2$, rather than on net utilization studies.
 - \dagger Data based on appearance of $\rm ^{14}CO_{2}$ from $\rm ^{14}C\text{--}labelled$ substrate.
 - # My unpublished results.

In this context then, the overall relationship between Δ oxygen consumption (or Δ carbon dioxide production) and a net sodium transport need not show the energy requirements for sodium transport. Indeed, Maffly and Edelman¹⁸ have shown that in the toad bladder increments in net sodium transport are related to $\Delta Q o_2$ when pyruvate is the added substrate. In contrast, addition of acetate increases Qo2 without any increment in net sodium transport. Obviously, Δ sodium transport/ ΔQ_{O_2} (or Δ sodium transport/ ΔQ_{CO_2}) is different for acetate and for pyruvate. In the absence of information about the intracellular organization of the specific exergonic reactions which are linked to sodium transport, little further understanding can be obtained about mechanism or actual energy requirements for sodium transport by relating either $\Delta \dot{Q} co_2$ or $\Delta \dot{Q} o_2$ to Δ sodium transport.

The results of experiments on the quantities of both the specific substrates taken up by and the individual products leaving a tissue simultaneously would aid an understanding of the significance of the respiratory quotient of an organ. Most important, this might perhaps permit the identification of specific reactions which have sufficient free energy changes to drive sodium transport.

Arrangement of Cholinoreceptors on the Neuronal Membrane of Two Pulmonate Gastropods

CHOLINERGIC transmission has been demonstrated in ganglia of some gastropod molluscs1,2. The large neurones of gastropods are very suitable for investigation by the microelectrode technique, and use of this method to compare the activity of cholinergic drugs of different chemical structure can reveal new facts about the occurrence and arrangement of active groups on the cholinoreceptive membrane.

We used the freshwater gastropod molluses Planorbis corneus and Limnaea stagnalis. Most of the neurones in the ganglia of these molluses are spontaneously active. The membrane potential is 40-60 mV and the action potential is about 100 mV. Addition of acetylcholine either to the perfusion fluid or by electrophoretic microapplication causes depolarization and an increase in spike frequency in most of the cells. Some cells respond to acetylcholine by hyperpolarization and a decrease in spike frequency. Some cells are unaffected by acetylcholine3. The action of different cholinomimetics and cholinolytics suggests that the cholinoreceptors are nicotinic ones resembling somewhat the receptors of mammalian skeletal muscle4. The cells which respond to acetylcholine by depolarization are very sensitive to stimulation by nicotine but do not react to arecoline at all; they are more sensitive to butyrylcholine than to methacholine bromide; d-tubocurarine and gallamine exert a strong cholinolytic action, but atropine and ganglion blocking agents are almost inactive.

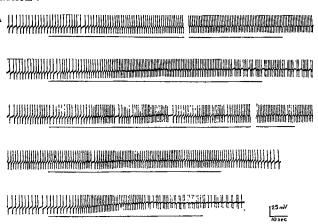

Mammalian skeletal muscles are known to be very sensitive to bisquaternary compounds which have an internitrogen chain containing nine or ten atoms (about 14 Å); these are decamethonium, suxamethonium,

d-tubocurarine and gallamine. High sensitivity has also been shown for bisquaternary compounds which have a chain containing sixteen atoms (about 22 Å) between nitrogen atoms; these are hexacarbacholinobromide, prodecomium bromide, hexadecamethonium, the compound KB-72, the dicholinic esters of higher dicarbonic acids (suberic and sebacinic) and others (see ref. 6). This suggests that there is a definite arrangement of single receptors on the postsynaptic membrane. In some cases, the distance between the anionic points of neighbouring receptors is about 14 Å ("C-10 structure"), in other cases it is about 22 Å ("C-16 structure"). The C-16 structure seems to appear earlier in the development of the locomotor muscles than does the C-10 structure. The C-16 structure is probably more universal, for the signs of its presence are found not only in the muscles but also in the mammalian autonomic ganglia5.

Is there some definite arrangement of receptors on the neuronal membrane of molluses? To answer this question we have investigated the action of some bisquaternary compounds with an internitrogen distance of 14 Å and 20-22 Å.

The isolated peri-oesophageal ganglionic ring was placed in a bath (about I ml.) and perfused with saline, at a rate of 15 ml./min3. The visceral and the large parietal ganglia were opened and a large cell (100-200µ) was impaled by a microelectrode filled with 2.5 molar potassium chloride (diameter of the tip about 0.5μ , R=15-60 megohms). The electrode was connected through a cathode follower to a d.c. amplifier and then to a cathode oscilloscope. The compounds to be studied were added to the perfusion fluid; in some experiments, acetylcholine was microapplied electrophoretically.

Decamethonium and suxamethonium (internitrogen distance 14 Å) caused only slight depolarization and a small increase in spike frequency even in a concentration of $5 \times 10^{-5} - 2 \times 10^{-4}$ molar. The cholinomimetic effect of these drugs was 20-50 times weaker than that of acetylcholine and approximately equal to that of tetramethylammonium (Fig. 1A). The antiacetylcholine action of decamethonium and succinyldicholine was also very weak. curarine and gallamine possess a strong antiacetylcholine action4.

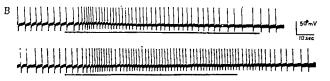

Fig. 1. A, The action of decamethonium (C-10), succinyldicholine (D-2), tetramethylammonium (TMA), suberyldicholine (D-6) and acetylcholine (Ach) on the same neurone *Planothis*. B, The action of sebacinyldicholine (D-8) and acetylcholine. In A and B the time during which the drug was applied is shown by the lower trace. Intervals are indicated by interruptions: in the case of C-10, 90 sec; in the cases of TMA and D-8, 30 sec. Here and in Fig. 2 the amplification was large. Only the lower part of spikes can be seen.

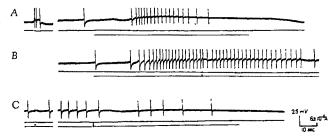

Fig. 2. The action of acetylcholine and of the compound KB-72 on neurone *Planorbis*. Acetylcholine was added to the perfusion fluid or applied by 600 msec pulses (see middle trace). A, The action of acetylcholine. B, The cholinomimetic action of KB-72. During the perfusion with KB-72 acetylcholine was applied twice. C, The action of acetylcholine (microapplication and adding to the perfusion fluid) after perfusion with KB-72 for 5 min.

Thus the results obtained with tubocurarine and gallamine suggest that there is a C-10 structure on the neuronal membrane, but the results with decamethonium and succinyldicholine show no evidence of this structure. We think that the results obtained with depolarizing drugs are much more important. Cholinomimetic action requires more precise complementarity to the cholinoreceptive surface than cholinolytic action. The high potency of tubocurarine and gallamine can be explained not by the presence of two nitrogen atoms but by other molecular features which can favour the firm binding to the receptive membrane. Such features would be the size of their molecules, the presence of flat rings and so For example, tubocurarine has a strong ganglion blocking action although there is no C-10 structure in the autonomic ganglia.

Dicholinic esters of suberic and sebacinic acids (internitrogen distance 20 Å-22 Å) exerted a very strong cholinomimetic effect on the neurones of Planorbis (Fig. 1A and B); their effect was usually stronger than that of acetylcholine. Depolarization and the increase in spike frequency induced by suberyldicholine and sebacinyldicholine lasted longer than when induced by acetylcholine, and desensitization was less pronounced.

Another compound with about 20 Å between nitrogen atoms, KB-72, a depolarizing myorelaxant⁸, induced depolarization and an increase in spike frequency in neurones of Planorbis. KB-72 was nearly as potent as acetylcholine but its effect developed later and lasted longer (Fig. 2). KB-72 also had a strong antiacetylcholine action: it prevented stimulation by the latter (Fig. 2C).

These data suggest the existence of C-16 structure on the neuronal membrane of Planorbis: a mutual disposition of receptors with about 20 Å between the anionic points of two neighbouring receptors In the neurones of Limnaea stagnalis suberyldicholine was about five times less active than acetylcholine There is still no clear evidence of the existence of a C-16 structure in this species; perhaps only a small part of cholinoreceptors is arranged in C-16 structure.

Rapid Reflex Interference with Peripheral Vascular Tone

THE prevalent conception that blood vessels are only capable of contracting and dilating slowly is based on the behaviour of excised segments^{1,2}. Under natural conditions, however, far more rapid vascular activity has been observed. The veins of the bat's wings³, the arterio-venous anastomosis in the rabbit's ears⁴ and the arteries in the conjunctiva in man⁵ are such examples.

The so-called atrial waves, which have been observed in the peripheral circulation in connexion with the atrial systole⁶, are another example of rapid vascular behaviour. It has been taken for granted that these waves are transmitted mechanically. A study of the atrial waves some years ago⁶ indicated, however, that they were transmitted not mechanically but nervously, because they seemed to be uninfluenced by friction and damping and did not follow hydrodynamic laws for wave transmission; moreover, they could be wiped out by nerve block.

These studies were based principally on records of the arterial pulse in the arm. Finger plethysmography of

standard type, has since been used, because it was expected that the atrial waves could be traced in the digital vasculature, which is controlled to a great extent by the nerves, besides being a playground for all kinds of vasomotor reactions. The results confirm that the atrial waves are transmitted by reflex, not mechanical, means; thus as a rule they are more distinct in the fingers than in the brachial or radial arteries and can be recorded in the finger even when the arm circulation is occluded (results to be published) (Figs. 1 and 2). This vascular reflex mechanism involves the baroreceptors in the atrias and roots of the large veins 10 and their afferent fibres, the efferents being the sympathetic fibres to the smooth vascular muscles.

Pressure was applied to the carotid sinus in order to see whether reflex effects of a similar type could be experimentally produced by the stimulation of proprioceptors in other cardio-vascular areas. A series of experiments on healthy persons (results to be published) showed that there is a rapid and transient volume increase of the finger, corresponding to the atrial waves in connexion with the carotid sinus pressure. The arterial pressure is not affected by this brief pressure and the reaction is sometimes seen even when the circulation in the arm is obstructed by a cuff on the upper arm.

Experiments were then performed during the catheterization of patients for diagnostic purposes (results to be published) to see if brief distension of the central blood

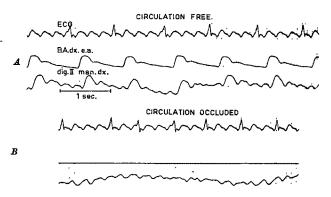

Fig. 1. Atrial flutter in a man aged 46. A, Upper tracing ECG with flutter waves, lower tracing finger plethysmogram with distinct atrial waves of the same frequency and duration as flutter waves in ECG, middle curve less distinct atrial waves in extra-arterially recorded pulse curve from brachial artery. B, Circulation occluded by cuff on upper arm. Atrial waves still distinct in finger plethysmogram while they are wiped out in peripheral pulse.

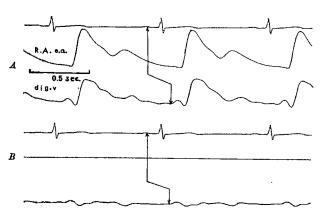

Fig. 2. Healthy man with sinus rhythm. A, Distinct atrial waves in plethysmogram (bottom curve), less distinct waves in extra-arterially recorded pulse curve from radial artery (middle curve). Transmission time of atrial wave as measured from beginning of atrial mechanic systole (approximately 0-05 sec after beginning of P-wave in ECG) to up-stroke of atrial wave about 0-20 sec (arrow). B, Circulation occluded by cuff on upper arm. Atrial waves still distinct in finger plethysmogram. Transmission time unchanged.

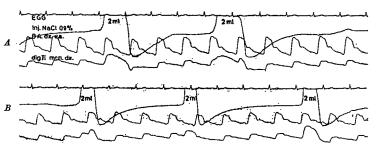

Fig. 3. A, Effect of flushing catheter with 2 ml. of saline, tip of catheter in vena cava inferior near atrial entrance. Volume increase of fluger shortly after beginning of each flushing (lower curve), no response in extra-arterially recorded pulse curve from brachial artery. B, Same effect with tip of catheter in external lliac veln.

vessels produced the same volume variation of the finger as the atrial systole and pressure on the carotid sinus. This was found to be the case, as seen in Fig. 3.4, which shows a rapid and transient swelling of the digit in connexion with the flushing of a catheter placed with its tip at the atrial entrance of the inferior vena cava. This is thus an imitation of the effect of the atrial systole.

The reaction was also seen during obstructed circulation. Sometimes a mere poking of the vessel wall with the tip of a catheter elicited a distinct volume reaction in the finger. The reflex time, which is the same for the atrial waves, the reaction to carotid sinus pressure and the intravascular flushing, is remarkably short—only a few tenths of a second (Fig. 2).

The reaction was elicited when the catheter was flushed with its tip placed in "classie" baroreceptor areas¹⁰, for example, the root of the inferior vena cava and the root and arcus of the aorta—but it was also elicited when the tip was placed in abdominal arteries and veins, as in Fig. 3B. Stretch receptors of the Vater–Pacini type have been shown to be embedded in and around the adventitia of such vessels¹¹. They are very sensitive to deformation¹² and bursts of spikes have been recorded from their afferent fibres in connexion with the rise in systolic pressure¹³. It is possible that their reflex effects, hitherto unknown, are the ones demonstrated here.

In conclusion, it can be said that there are signs of a rapid reflex interference with the peripheral vascular tone, produced by the stimulation of well known as well as less acknowledged reflexogenic areas of the cardio-vascular system. These effects can be traced in peripheral arteries. but they are more distinct in small, nervously controlled blood vessels such as the finger vasculature. The effects on the digital volume are small but may be theoretically important, for they signify that a co-

ordination is possible between the heart beat and the peripheral vascular tone.

Influence of Hypoxia on Glucose Transport across the Human Placenta

EXPERIMENTAL models for foetal hypoxia have predominantly employed acute asphyxiation1,2, although in the human it is likely that when impairment of foetal oxygenation does occur it is often chronic and incomplete3. It has been shown4 that by giving mothers 10 per cent oxygen to breathe (for short periods of time) it is possible to halve foetal oxygen tension without harming the foetus. This experimental technique was used to study glucose and acid-base status in mother and foetus during hypoxia.

Five conscious patients at term in the first stage of labour were given a mixture of 10 per cent oxygen and 90 per cent nitrogen to breathe through the anaesthetic face mask for periods of 15-30 min. Maternal and foetal blood samples were collected simultaneously before and towards the end of the 10 per cent oxygen administration. Prompted by some unexpected results we also sampled maternal and foetal blood in five other patients before and 20 min after an intravenous injection of 10 g of glucose in 20 ml. of water. The maternal samples were taken from the fingertip after warming at 40° C for several minutes; the foetal capillary samples were collected from the scalp by the method of Saling⁵. All blood was collected in fine nylon tubing containing a heparinized thread. Oxygen and carbon dioxide pressures and pH were measured within 5 min of collection using an I.L.-113 ultramicroelectrode assembly at 38° C. Base excess was calculated from the Severinghaus nomogram after correcting for percentage oxygen saturation of haemoglobin⁶. Foetal haemoglobin was assumed to be 15 g per cent. Blood for glucose estimation was transferred to small tubes and mixed with sodium fluoride. After microcentrifugation, the glucose concentration in the plasma was estimated by a microadaptation of the technique described by Keston and Teller. The confidence limits of the methods for measuring glucose and oxygen have been described^{4,10}.

The effects of breathing 10 per cent oxygen are summarized in Table 1. Maternal blood glucose increased in every patient, the mean change being +34.6 mg per cent (t, 8.28; P < 0.001). Foetal blood glucose either remained constant or decreased (t, 1.59; P > 0.25). Oxygen tension was halved in the mothers, the mean change being -43 mm of mercury (t, 7.80; P < 0.002). It was

significantly lowered in the foetal samples, the mean change being -8.3 mm of mercury (t, 4.60; P < 0.02). When further measurements were made in one patient, E, 15 min after the end of the experiment, the oxygen tensions had reverted to baseline values. A slight decrease in carbon dioxide pressure, not statistically significant, occurred in all patients and could be explained by the overbreathing which we observed. There were no consistent changes in pH or base excess.

^{*} Injected intravenously.

In order to discover the expected change in foetal blood glucose for a rapid maternal rise of 30-40 mg per cent, a further five patients were given 10 g of glucose intravenously. The results summarized in Table 2 show that similar changes occur in both maternal and foetal blood. The mean maternal increase was 34 mg per cent (t, 13.41; P < 0.001) and the mean foetal rise was 33.2 mg per cent (t, 11.01; P < 0.001). The changes in blood glucose in the two series of experiments are compared in Table 3: Δ M1, Δ M2 and Δ F2 are very similar, but a t test applied to $\Delta F1$ and $\Delta F2$ shows that these values are significantly different (t, 9.05; D.F., 8; P < 0.001).

M, Difference between maternal blood glucose concentrations before and after either 10 per cent oxygen or 10 g of glucose. F, Difference between feetal blood glucose concentrations before and after either 10 per cent oxygen or 10 g of glucose. F_1 compared with F_2 : t, 9-05; D.F., 8; P<0-001.

The dissociation of foetal and maternal glucose concentrations during the period of hypoxia was unexpected. Normally foetal and maternal glucose concentrations are closely correlated, with maternal greater than foetal. This has been confirmed for foetal and cord blood^{9,10}. Changes in maternal blood glucose are transmitted to foetal blood: large rapid increases in glucose concentration (+160 mg per cent) caused by the intravenous injection of 50 g of glucose to the mother caused a comparable change in the foetus (+155 mg per cent)10. Ely11, in her study of the placental transfer of hexoses in the guineapig, showed that the spontaneous fluctuations in maternal glucose concentration which occur under light anaesthesia are quickly reflected in the solution perfusing the foetal aspect of the placenta. In our experiment, maternal glucose concentration increased without producing the expected foetal increase. There are three possible explanations: (1) glucose does not cross the placenta during the period of hypoxia; (2) glucose does cross the placenta but its effect on foetal glucose concentration is eliminated by an increased use of glucose somewhere in the foetus or placenta; (3) an increase in the concentration of foetal blood glucose is cancelled out by haemodilution.

The third explanation is the least likely. Although no direct measurements of haematocrit were made, hypoxia is known to cause haemoconcentration rather than haemodilution in adult and foetal animals of several species12. The possibility that there was increased glucose utilization during the hypoxic period cannot be dismissed, but there is no direct evidence of such an increase. If there had been a shift to anaerobic metabolism by the foetus or placenta with increased glucose utilization (because of the inefficiency of glycolysis as an energy source), nonbuffer tissue acid production would have caused some degree of metabolic acidosis. No consistent changes in pH and base excess occurred in the foetus. The changes were similar to the maternal changes in every case and gave no indication of a qualitative difference between maternal and foetal responses to hypoxia. Huckabee¹³ found that in human volunteers breathing low oxygen mixtures there was a critical arterial oxygen pressure (26-32 mm of mercury) below which "excess lactate" (which he regarded as the most sensitive index of the shift to anaerobic metabolism) accumulated. It is of interest that the two patients (B and C) in whom the base excess and pH did fall were those in whom the maternal oxygen tensions, 24 and 31 mm of mercury, fell below Huckabee's critical threshold. The phenomenon of dissociated maternal and foetal glucose changes, however, occurred in all patients, not only those with an associated metabolic acidosis.

Increased glucose utilization would occur with increased oxygen consumption, but the effect of hypoxia in several species including the human neonate is to decrease oxygen consumption¹⁴. Changes in temperature which alter oxygen consumption in the neonate cannot¹⁴ be invoked when the foetus is in utero.

Hypoxia has been thought to have no effect on transplacental passage of sugars. Karvonen $et\ al.^{15}$ measured

the rate of disappearance of non-metabolized sugars from the foetal circulation of the guinea-pig when the mother was given 10 per cent and 80 per cent oxygen. Varying the concentration of inspired oxygen did not alter the rate of transfer. Transport of glucose across the guinea-pig placenta shows a tendency to saturation at high concentrations, competitive inhibition of fructose and galactose and movement against a concentration gradient in experimental glucose/galactose competition, which suggest that a selective carrier mechanism is involved11. The energy requirements of such a system with transfer usually down a concentration gradient are so far unknown. It would be unremarkable if the system had some minimum requirement for oxygen. If the transport of glucose were an oxygen-dependent process, the failure of foetal glucose to increase concurrently with maternal glucose during

moderate hypoxia would be explained.

Comparison of Tables 1 and 2 shows that the baseline foetal oxygen tension (10 mm of mercury) in patient H given 10 g of glucose is as low as the lowest value produced

by maternal 10 per cent oxygen inhalation in patient B. When the maternal oxygen tensions are compared they are seen to be 109 and 24 mm of mercury, respectively. Maternal rather than foetal hypoxia seems to be the relevant factor in reducing glucose transfer.

We thank the technical and medical staff of this department for their help. This work was aided by a grant from

the Felton Bequest.

Olfactory Coding

OLFACTORY signals must be coded both externally and internally. Externally, the odorous molecules present distinctive patterns based on their ability to excite several more or less widely separated intervals in a linear continuum of osmic stimuli^{1,2}. In other words, each odorous molecule carries a characteristic combination of primary stimuli. Internally, the characteristic pattern of the stimulus molecules must be transformed into a patterned neural discharge which somehow reflects the specificity of the input signal from the odorous molecules. To solve the olfactory code, we must find a correlation

Correlation curve for the response of the rabbit. B, Benzaldehyde; C, camphor; F, fenchone; M, methyl salicylate; P, pinene.

between physically observable properties of the external stimulus and the internal response,

In the odorous molecules there is evidence that the different primary stimuli are related to the various low vibrational frequencies of the molecule^{1,3-5}. At the level of the sensory end organs, the coding appears to be effected by the more or less selective stimulation of certain types of receptors, so that the kinds of receptor that "fire" depend on the quality of the stimulus and the number that "fire" depends on its intensity^{1,2,6}. The signals then pass by parallel connecting fibres to the olfactory bulb^{7,8}. There, the signals are transformed into a system of frequency components the numerical values of which represent the quality and the amplitudes of which represent the intensity of the stimulus^{8,10}.

This is shown by experiments with stainless steel macroelectrodes implanted at several places (usually four) in the olfactory bulbs of rabbits or, more recently, some human subjects, so that the discharges resulting from various kinds of smell stimuli can be recorded on magnetic tape. With conscious subjects, the bursts of activity continue for several seconds and can be electrically analysed to identify the frequency components present in the discharges evoked by different smells. The results show that the frequency components are distinctive according to the stimulus category, that is, substances with a certain type of odour (such as peppermint or musk) have many of the same frequency components in the discharge.

If the external stimuli are distributed along a linear continuum of possible molecular vibration frequencies, and if their internal counterparts are frequency components

in a continuum of possible frequencies in the discharge passing from the bulb to the higher centres of the brain, it is reasonable to look for a systematic relation between particular features of the input from the environment and corresponding features in the signals passed on into the brain. There should be a correlation between particular vibration frequencies in the stimulus molecules and certain frequency components in the response, and this correlation should be the same for chemically distinct stimuli. There appears to be a correlation.

For benzaldehyde and anisole, detailed information is available about the "normal modes" of the molecules, so that we seem to have full details of their vibration frequencies including the "difference frequencies" which are generated when two normal modes are excited in the same molecule at the same time. Table 1 shows the low molecular vibration frequencies of these two compounds together with all the high amplitude frequency components and certain of the weaker ones (of which there were many) in the responses of a rabbit to benzaldehyde and of a man to both benzaldehyde and anisole.

Fig. 1 shows a correlation curve for the responses of the rabbit which was constructed by plotting all the vibration frequencies for benzaldehyde against the frequency components in its response and drawing the smooth curve which could be made to pass near the largest number of points with the least curvature. For four additional test compounds, detailed normal mode assignments were not available, but far infrared spectra showing distinct peaks were secured using a Perkin-Elmer Model 301 far infrared spectrophotometer. These provide a partial inventory of the molecular vibration frequencies of these substances. With fenchone, camphor and methyl salicylate, all the far infrared frequencies below about

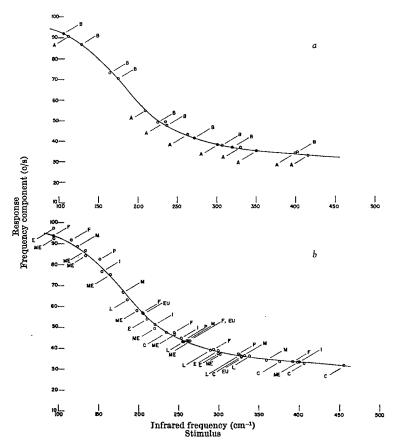

Fig. 2. a, Correlation curve for the response of L. H. A, Anisole; B, benzaldehyde. b, The same curve with data for nine additional compounds superimposed. C, Citral; E, eugenol; EU, eucalyptol; F, fenchone; I, indole; L, limonene; M, methyl salicylate; ME, menthol; P, phenylacetic acid.

450 cm⁻¹ can be correlated with frequency components in the discharge by the same curve (after a small adjustment in the middle range) to give the result shown in Fig. 1. The spectrum of pinene has eight distinct peaks between 450 and 100 cm⁻¹ of which five are correlated in Fig. 1.

Fig. 1.

We used the same method for the human subject, L. H., except that the preliminary curve was based on vibrational data for both benzaldehyde and anisole to give the result shown in Fig. 2a. It embodies all the molecular vibration frequencies of benzaldehyde between 425 and 100 cm⁻¹ and nine of the eleven anisole frequencies in the same range. In Fig. 2b far infrared and frequency component data for nine additional compounds are superimposed on the same curve without any adjustment.

Most of the molecular vibration frequencies can be correlated systematically with frequency components in the discharges from the olfactory bulb and usually with the strongest of these components, and the correlation is independent of the chemical identity of the stimulus molecules. The fact that both the rabbit and the man showed frequency components with no corresponding molecular vibration frequency is probably the result of contamination because the odorous stimuli were presented at a high concentration and without special purification. Also, as pointed out elsewhere, not all molecular vibrations are necessarily osmically active11,12.

Thus there seems to be a one to one relationship between properties of the stimulus and properties of the response to olfactory signals, both of which are objectively observable, and the way is open to a detailed exploration of the olfactory code.

These correlation curves are not the only smooth curves which can be drawn when all the frequency components are plotted against all the molecular vibration frequencies, but the number of possible alternatives is not large, and none of the others includes as many molecular frequencies

or as many of the strong components of the responses.

It is perhaps unfortunate that the word "frequency" should apply to both the stimulus and the response, and it must not be supposed that the vibrations of the odorous molecules excite nerve discharges of any physically related frequency by some process of direct mechanical coupling. All that can be said is that a particular vibration frequency in the molecule enables it to "fire" one kind of receptor but not another, and the receptors use a frequency coding of a very different sort to distinguish their signals from those of receptors of other types.

PSYCHOLOGY

Degree of Learning, Proactive Interference and Retention

It is well known that retention of verbal material declines with the number of lists learnt1 if all lists are learnt to the same criterion. Underwood¹ concluded from this that the decline in retention is caused by proactive interference from the material previously learnt. This conclusion, however, has been questioned by Warr^{2,3}, who reports that the number of trials to reach a standard criterion decreases with successive lists (a finding also due to Deutsch and Mamakos4), and suggests therefore

that the decline in retention is caused by the decline in degree of learning. In support of this argument he presents data showing that, when successive lists are practised, not to a criterion but for a constant number of trials, the usual decline in retention over successive lists fails to If, however, degree of learning is the most important factor determining retention over successive lists, there should have been an actual increase in retention in Warr's experiment, for the degree of learning increases with successive lists when number of trials is held con-In the present experiment, we investigated retention over successive lists with degree of learning experimentally held constant.

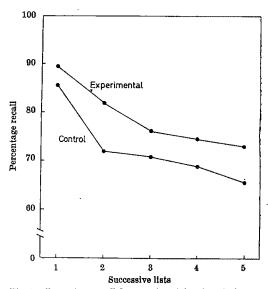

Fig. 1. Percentage recall for experimental and control groups.

The experimental procedure was modelled on that of Warr^{2,3}. The material to be learnt consisted of five lists of twelve pairs of two syllable adjectives taken from the lists compiled by Melton and Safier. The subjects were two groups of eight university students, who learned the lists by the method of anticipation. Exposure time for the stimuli was 2 sec and the intertrial interval 30 sec. Successive lists were learnt at 24 h intervals and testing for retention conducted 24 h later, immediately before the next list was learnt. Retention testing was conducted in the same way as original learning, except that response items were not presented and only one trial was given. The control group learned each list to a criterion of a single trial with all items correct. The experimental group learned the first list to this criterion, but on subsequent lists learning trials were continued until the subject had made the same total number of correct anticipations (Warr's^{2,2} operational definition of "degree of learning") as on the first list.

14	Table I		List		
	1	2	3	4	5
Mean trials to criterion	11-13	9.63	8.25	7.25	6.75
SD	5.25	4.38	4.97	3.60	8.25
Mean correct anticipations per item	6.39	5.74	4.74	4.51	4.51
SD	2.43	2.08	2.29	1.71	1.74

mobio 1

As in Warr's experiments, the control group showed an increase in speed of learning successive lists, and a consequent decrease in degree of learning: Table 1 presents mean trials to criterion and mean anticipations per list item for each list. Fig. 1 shows percentage recall for each list in both groups. The decline in performance shown by the control group is very similar to the result obtained by Warr3: from 85.5 per cent correct on list 1 to 65.7 per

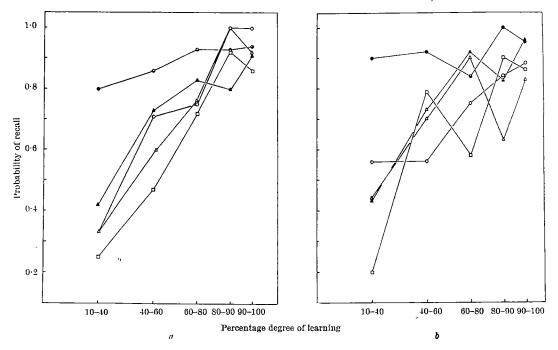

Fig. 2. Relationship between probability of recall and percentage degree of learning for a, control group and b, experimental group. List 1; ▲, list 2; ○, list 3; △, list 4; □, list 5.

cent on list 5 compared with his 82.5 per cent (list 1) to 60.8 per cent (list 6). More important, a decline of a comparable order is shown by the experimental group: 89.6 per cent (list 1) to 73.0 per cent (list 5). Analysis of variance of the data presented in Fig. 1 shows the decline in performance over successive lists to be significant (F, 6.12; df, 4 and 56; P < 0.01), but there is no significant variation caused by either experimental treatment or the interaction between treatment and lists. It seems reasonable to conclude therefore that previous learning of similar material can depress retention even when degree of learning is controlled. A factor rather like the proactive interference stressed by Underwood¹ is thus seen to be of some importance.

Nevertheless, it is clear from our data that the factor of degree of learning emphasized by Warr is also important in determining retention. Figs. 2a and b show the relationship between probability of recall and percentage degree of learning. (To obtain the latter, the number of correct anticipations made by a subject to each item in the list is expressed as a percentage of the maximum number of correct anticipations made by that subject to any item in that list (see ref. 3).) In order to have roughly equal numbers of readings at each point plotted in Figs. 2a and b, values on the abscissae are grouped in the ranges: 10-40 per cent, 40-60 per cent, 60-80 per cent, 80-90 per cent and 90-100 per cent. It can be seen that, in both groups, there is little relation between degree of learning and probability of recall on the first list. In the control group, the effect of degree of learning becomes greater on successive lists. The effect of proactive interference is seen in the fact that, for a given degree of learning, probability of recall is lower the later the list—a finding reported befores. In the experimental group, however, the relationship between degree of learning and probability of recall is more obscure, only the lowest level of degree of learning having a very obvious effect. Productmoment correlations were calculated for the two groups between percentage degree of learning (ranked 1 to 5 as in Figs. 2a and b) and probability of recall, irrespective of list, yielding the following results: for the control group r, 0.81; for the experimental group r, 0.62; P < 0.001in both cases.

These data suggest that proactive interference is a very important determinant of retention of verbal material, able to exert its effects even when degree of learning is experimentally controlled. If, however, degree of learning is not very high, the effect of proactive interference is chiefly exerted on those items with the lowest degree of learning.

GENERAL

Amazing Antiquity of Mining in Southern Africa

THE only ancient manganese mine yet recorded is in southern Africa, at Chowa near Broken Hill, Zambia1. Its rubble infilling contained crudely flaked mining tools chiefly of manganese, used as choppers, wedges and chisels, together with hammerstones, perforated stones, upper and lower grindstones and a single polished stone axe, but no metal objects or potsherds. The Kafulamadzi Hills 3 miles away revealed Later Stone Age assemblages in quartz, together with manganese tools identical to those found in the working. On this basis, Dart postulated in 1934 the existence of stone age mining in southern Africa.

In 1964 Boshier conducted trial trenching in workings at the Ngwenya Iron Mine in western Swaziland. Sites there yielded flaked stone mining tools similar to those from Chowa found in 1934 (ref. 2).

So far forty excavations have been completed, seventy collections made and 300,000 artefacts recovered. It has unexpectedly emerged at Ngwenya, particularly from the site called Lion Cavern, that the mining is of

great antiquity.

Lion Cavern is at the southern end of a steep scarp face of the haematite hill, Lion Peak, where ancient miners cut into the face of a cliff, more than 500 ft. high, a shelter-shaped working about 25 ft. wide, 30 ft. deep and The floor of the shelter was covered by 20 ft. high. haematite soil and rubble. The first excavation, just inside the cavern's drip-line, bordered on the inner aspect of a large 5 ton haematite boulder fallen from above and almost blocking the entrance to the cavern.

The deposit, 9 ft. deep in this area, had the following characteristics: (a) 0-7 ft. contained stone-mining tools with a few sherds, which were restricted to the upper 4 ft.; (b) 7 ft. of worked bedrock 9 ft. down contained an atypical assemblage of stone artefacts chiefly quartzite and quartz. Irregular flakes predominated, and there were a few chisels. The industry was ascribed provision-

ally to the Later Stone Age.

Dr Minze Stuiver gave as the date³ for the basal level Y-1713, 9640 ± 80 B.P./ 7690 ± 80 B.C. We therefore decided to remove the obstructing haematite boulder by undercutting it on its talus-slope side and excavated the underlying deposit. Here the deposit had a maximum depth of more than 11 ft., with details as follows: (a) 0-6 ft. contained a few mining tools; (b) 6-8 ft. contained undoubted Middle Stone Age artefacts and possible Later Stone Age tools; (c) 8 ft. of worked bedrock deeper than 11 ft. yielded 23,000 artefacts belonging unquestionably to a middle stage of the Middle Stone Occasional stone mining tools were also found. Well defined ash levels showed that the assemblage was in situ.

Quartz, white quartzites, grey and white dappled quartzite, black indurated shales and greenish cherts were the principal materials used by the miners. These rock types occur mostly on a ridge overlooked by, and about 0.25 miles from, the cavern. The exposures there are patently flaked. Dappled grey and white quartzite exposures occur about a mile and more northwest of the site.

Samples of charcoal nodules from the middle to lower levels of the Middle Stone Age level were sent to the Yale and Groningen Laboratories, and the following dates were given:

```
Y - 1827
                 22,280 \pm 400 B.P./20,330 \pm 400 B.C.
GRN - 5020, 28,130 \pm 260 \, \text{B.p.} / 26,180 \pm 260 \, \text{B.c.}
```

The dates harmonize with the archaeological evidence and suggest that there was mining here for a very long time, terminated perhaps by the fall of the haematite block.

Mr John Strathern, chief geologist at the mine, confirmed the artificial nature of the rock surface underlying the Middle Stone Age stratum. He classified the bedrock as a specularite-rich, crumbly greasy red haematite, and stated that plain crumbly greasy red haematite occurs in large areas and in far more easily accessible locations at Castle Peak, only half a mile to the south. He therefore considered specularite to have been the incentive for the concentration of mining at Lion Cavern.

The worked floor must extend for at least another 10 ft. beyond the outside edge of this second excavation. Its outer part, as yet unexcavated, may date back another few thousand years. Evidence of an earlier culture may also be located there; there is an enormous Later Acheulian site, estimated to contain ten million artefacts barely a mile away.

At least 50 tons of haematite rich in specularite must have been removed from Lion Cavern; two-thirds of it during the Middle Stone Age. Boshier found it was held traditionally in high regard by Swaziland counsellors.

Haematite and specularite occur at many sites ranging back to Earlier Middle Stone Age times within 20 miles of Ngwenya.

These datings demonstrate that haematite has been mined at Ngwenya, on and off, for at least 28,000 vr. They afford the first dated presumptive evidence that all foreign ores and pigments found in prehistoric deposits all over the world were the result of deliberate mining. Dates of cavern strata containing haematite in Rhodesia and South Africa have ages ranging from 37,000 to 42,000 B.P. Incidentally, the claim made almost 35 vr ago, that 'manganese was being deliberately mined in Zambia by a foreign people familiar with its potentialities in Late Stone Age times", and Boshier's expectation2 that "In this field (of ancient mining) Bomvu Ridge (Ngwenya) is of supreme significance; its thorough investigation might well furnish us with knowledge of the genesis of South African mining", have been fully justified. We thank A. McKerron, N. A. D. Campbell and A.

Boshier for showing us the potential of Ngwenya; the staff of the Swaziland Iron Ore Development Company for their help; Dr Minze Stuiver, director of the Yale Radiocarbon Laboratory, and Dr J. C. Vogel, director of the Groningen Laboratory, for dating; and the Anglo-American Corporation of South Africa and the Swaziland Iron Ore Development Company for financial support.

Amino-acid and Peptide Synthesis from Hydrogen Cyanide

THE recent interesting findings of Matthews and Moser¹ and the earlier work of Lowe et al.2 involving the abiogenesis of amino-acids and their precursors from simple molecules (HCN, H₂O, NH₃) raise two important issues which stem from my observations3 of the amino-acid content of atmospheric precipitation.

First, abiogenic processes leading to amino-acid systems are usually considered in connexion with remote times, yet amino-acids and their precursors can be detected in rainwater and snow, and the experiments carried out so far indicate at least the possibility that their genesis

may be abiogenic.

Second, both groups of investigators subject their systems to acid hydrolysis by refluxing with azeotropic hydrochloric acid. Unless this acid is freshly distilled before use, however, it will be found to contain small amounts of amino-acids after reflux—a phenomenon which itself is worthy of further study. I do not mean to suggest the invalidation of the hydrogen cyanide synthesis of amino-acid systems, but simply that a reappraisal of the data may be useful.

BOOK REVIEWS

ALGEBRAICAL GENIUS The Mathematical Papers of Sir William Rowan Hamilton

Edited by H. Halberstam and R. E. Ingram. Vol. 3: Algebra. (Cunningham Memoir, No. 15.) Pp. xxiv + 672. (London: Cambridge University Press, 1967.) 210s. net. Hamilton's decisive contribution to algebra is his discovery of the quaternions. It is the source from which modern algebra has derived some of its most fertile ideas and methods: the freedom to discard the commutative law of multiplication and the rigorous construction of new algebraical systems from those already known, thus putting algebra on a sound logical basis. Hamilton was deeply concerned about the foundations of algebra which, in his day, were considered to be far less secure than those of geometry. The introduction of negative numbers and, to a greater degree, of complex numbers appeared to be obscure and even illogical to many of his contemporaries (and perhaps still to some of our own). In a long essay, written in 1833, he propounds the seemingly bizarre doctrine that "algebra is the science of pure time"; in more prosaic language this means that he proposed to take the positive real numbers as a starting point whence the continuum of all real numbers, positive or negative, can be derived as equivalence classes of pairs of positive numbers, equivalent pairs having the same "difference". Granting now the real numbers, he proceeds to give his celebrated construction of the complex numbers as pairs of reals, obeying the multiplication law

$$(a_1,b_1)(a_2,b_2) = (a_1a_2 - b_1b_2, a_1b_2 + a_2b_1)$$

From there it was a natural step to pass to an algebra of triplets endowed with a product that preserves the usual rules of algebra. But for thirteen years Hamilton was held up by the fact (as we now know) that no "division algebra" of triplets can possibly exist. Time and again, after a night of strenuous efforts, his children asked him in the morning, "Papa, can you multiply triplets?", to which he replied, with a sad shake of his head, "No, I can only add and subtract them". It was on October 16, 1843, that "a spark flashed forth" and Hamilton discovered that a satisfactory multiplication could be found for quadruples, or quaternions, as he called them, rather than for triplets. He believed that this discovery was his greatest scientific achievement and he hoped that quaternions would turn out to be a powerful tool in dealing with geometrical and physical problems. He devoted numerous articles to the applications of quaternions, some of which contain results of remarkable elegance. Looking back, more than a hundred years after Hamilton's death, one would admit that the usefulness of quaternions fell short of his expectations despite isolated successes, which persist to our own days, in various branches of mathematics. On the other hand, the theoretical ideas which led him to his discovery had a more far-reaching influence on the development of algebra than might have been anticipated at the time.

The papers on quaternions and related topics occupy about three-quarters of this volume, the remainder being taken up by Hamilton's researches on the quintic, now mainly of historical interest, and his ingenious invention of the "icosian calculus", a precursor of modern graph theory exemplified by the network of edges on an icosahedron.

Hamilton's memoirs were composed in an age in which a scholar's time and a printer's wage were considered less precious than at present, and an author was at liberty to expound his work in full detail and to adorn it with personal digressions, usually cast in impeccable prose, which gave mathematical writings a much more personal flavour than is possible today. It is interesting to learn how deeply Hamilton was influenced by John T. Graves, whose name is not widely known to mathematicians of our time.

It need scarcely be stressed that the volume has been beautifully produced by the Cambridge University Press. The editors, Professor H. Halberstam and Dr R. E. Ingram, have provided a lucid introduction and valuable addenda, which round off the monumental work of one of the great creative minds in the history of the mathematical sciences.

W. Ledermann

PULSE COMPRESSION AND RADAR

Radar Signals

An Introduction to Theory and Application. By Charles E. Cook and Marvin Bernfeld. (Electrical Science; A Series of Monographs and Texts.) Pp. xvi+531. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.) 156s.

Modern radar systems, although they function in accordance with the same basic principles as the primitive radars of some twenty years ago, are a million times more sensitive. The use of larger aerial systems, higher operating frequencies, more powerful transmitters and receivers of lower noise levels have all contributed to the improvement, but the most important contribution has come from the realization, during the 1950s, that in pulsed radar the range resolution and accuracy are functions of the signal bandwidth and not of the transmitted pulse width. The maximum detection range can be obtained by using the maximum energy per pulse and thus the widest pulse in accordance with the energy requirements of the system or with the available transmitter power. Nevertheless, even after this pulse width has been chosen, it is still possible to satisfy the range resolution conditions by coding the transmitted signal with wideband modulation information. The extraction at the receiving end of the information does require, however, a more complex receiving system than that normally required for a simple pulse radar. Such a complex receiving system is called a matched filter processing system, and the signal processing generally implies operations performed on the received signal in the r.f. or i.f. portions of the radar receiver.

Both the concepts and techniques involved in the pulse compression, matched filtering radar signal processing system are fully described in Radar Signals. The first five chapters are devoted to the broad theoretical aspects related to matched-filter techniques, with detailed discussions of the principle of stationary phase, the radar ambiguity function, and parameter estimation. The next four chapters deal with specific radar waveforms, including the linear FM waveforms and discrete coded waveforms. In the final four chapters various practical problems associated with matched filter systems are considered. These include effects of distortion on matched filter signals, the design of lumped constant and ultrasonic dispersive delay lines, and the application of microwave and optical techniques to matched filter designs.

The text is addressed primarily to the systems engineer, and although it is extremely clearly and well written and amply supplied with more than 300 illustrations, it demands of the reader a fairly high standard of mathematical knowledge and acquaintance with waveforms and wave analysis. Each chapter is adequately supplied with a list of references, varying in number from eight to thirty-eight, and totalling 268. These, together with a bibliography of sixty-nine references and detailed author and subject indexes, indicate the care which the authors

and publishers have taken in the preparation of an up to date and comprehensive treatise on the subject.

The authors state in the preface that the volume is the outgrowth of a series of notes prepared for a graduate level course covering the theory, application and design of large time-bandwidth radar signals, given to co-workers at the Sperry Gyroscope Company, and they express the hope that it might be used as an introductory textbook for other students following such a course. Certainly each chapter is more or less complete in itself, as would correspond to a lecture course, but it is doubtful whether it would be suitable as a textbook for use in Great Britain. It is undoubtedly, however, an important contribution to the literature on radar engineering and an extremely valuable exposition of, and reference to, the present knowledge of complex radar waveforms.

S. Weintroub

ALL ABOUT ELECTRODEPOSITION

Fundamentals of Metal Deposition

By E. Raub and K. Müller. Translated from the German. Pp. viii+268. (Amsterdam, London and New York: Elsevier Publishing Company, 1967.) 125s.

This book is a welcome addition to the literature of electrodeposition in the English language. It should be of great value to students in this field and to many of those already in industry who wish to understand the important fundamental processes on which their technology depends.

The first two chapters deal with the physical chemistry of electrolyte solutions and fundamentals of electrode processes. These will provide useful revision for those with a good background of physical chemistry and sufficient coverage of the subject for those who have not. The third and fourth chapters are concerned with cathodic discharge processes and various aspects of the structure of electrodeposits. In the first of these the treatment of electrocrystallization does not seem to be fully up to date and the section on hydrogen deposition is disappointing. There are few references here to recent researches concerned with ad-ions, mechanisms of incorporation of deposited ions into the crystal lattice, surface diffusion and other growth processes. Details of information concerning the mechanistic steps in hydrogen deposition are also inadequate, as is the literature cited. The final chapters are concerned with the physical and chemical properties and the distribution of deposited metals on the cathode. These chapters are up to date and the section on microthrowing power and levelling is excellently presented and illustrated.

The literature cited is biased towards German publications and the research interests of the authors. This is not unreasonable in view of the authors' long experience and expertise in the field. The text is easy to read, excellently illustrated throughout, and the standard of translation is high. Despite the few criticisms made, this book should be found on the bookshelves of all interested in electrodeposition.

I. A. MENZIES

INTRODUCING CATALYSTS

Introduction to the Principles of Heterogeneous Catalysis

By J. M. Thomas and W. J. Thomas. Pp. x+544. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1967.) 120s.; \$21.50.

In the scope of a textbook of medium length, the authors have presented a comprehensive introduction to a subject which has many aspects. It differs from some previous texts, among them those to which the authors have referred in their preface, by the inclusion of a brief chapter on the selectivity of catalysts and a discussion of

stepwise heterogeneous reactions, and a substantial one which introduces the design of catalytic reactors. This unusual breadth of the discussion of the principles of catalysis has resulted from the collaboration of a chemist with a chemical engineer.

Other chapters present the theory of adsorption; experimental methods in the study of adsorption; porosity and surface area; the role of lattice imperfections; geometric and electronic factors; and the mechanism of typical heterogeneous reactions. The review of experimental aspects of adsorption includes accounts of several of the techniques which have been developed more recently, such as flash desorption, infrared absorption, slow electron diffraction and the application of nuclear magnetic resonance and electron spin resonance methods to heterogeneous systems.

In this book consideration has been given to metals, oxides and non-metals, whereas many previous studies have been biased to a particular catalyst type. Consideration of the diversity of catalysts has led the authors to lay particular stress on the environment of the atomic site of catalytic activity. This aspect of the theory of catalysis is increasingly attracting attention (for example, in the Faraday Society discussion in 1966) because of the contribution which ligand field theory has made to understanding of the transition complex in the surface of a solid.

The book is excellently presented, with copious references, especially in the experimental section, a good author index, and a subject index which, if used in conjunction with the list of contents, is comprehensive. It can be recommended to research workers who want an up to date manual of this topic, and will be found to be stimulating by many who are already well informed about heterogeneous catalysis.

A. COUPER

PHOTOCHEMISTRY TRIBUTE

Photochemistry and Reaction Kinetics

Edited by P. G. Ashmore, F. S. Dainton and T. M. Sugden. Pp. xvi+378. (London: Cambridge University Press, 1967.) 75s. net; \$13.50.

A NUMBER of authors have contributed to this volume, the common link being that most of them were former research students of Professor R. G. W. Norrish and three have made distinguished contributions in their own countries to fields of study closely related to the interests of Norrish. The book is therefore a spontaneous token of affection to a scholar and personality of world wide reputation.

The series of review type articles covers the principal interests of Norrish and is divided into two parts, one dealing with photochemistry, the other with combustion kinetics. Separating these parts is a review of polymer chemistry.

There are general contributions by W. A. Noyes and Bernard Lewis, who review the contributions to science which have been made by Norrish. These are followed by a discussion of photochemistry in the liquid phase in which the importance of "cage effects" is stressed, both in inorganic and organic systems. In the gas phase, photochlorination is fully dealt with and the now well established technique of flash photolysis is the subject of two contributions. This part concludes with a detailed chapter on energy transfer in molecular collisions. Norrish's contributions to polymer chemistry are examined in the light of current knowledge in a review which deals almost entirely with free radical processes.

The final part of the book, dealing with combustion, is introduced by Semenov and in four reviews gives a clear account of the broad outlines of a difficult field of research. The individual topics dealt with include the mechanism of hydrocarbon oxidation in the gas phase, the pheno-

menon of the cool flame, sensitization and inhibition of

ignition and pyrolysis of paraffins.

This book can certainly be recommended to all chemists; it provides an easily read account of so many important fields of study. It is well provided with references and illustrated by clear diagrams. The editors and authors have provided their former professor with a tribute which, I am sure, must give him great pleasure and which justly matches his own reputation. JAMES C. ROBB

CHEMISTRY OF COAGULATION

Blood Clotting Enzymology Edited by Walter H. Seegers. Pp. xii+628. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.) 220s.

In a sense this book is disappointing in that it does not, as its title suggests, devote much space to the enzymology of blood coagulation; instead this is a comprehensive review of the mechanism of blood coagulation from the particular point of view associated with Dr Seegers. It is unfortunate that the author has not given more space to comparing and contrasting his own view with that proposed by other workers, which he dismisses with the phrase ... it is speculative in nature and proposes a sequence of events that is not consistent with the known facts of prothrombin chemistry". It is, in fact, the chemistry of prothrombin which is at the very centre of the discord between Seegers and those other "speculators". believes that prothrombin isolated by procedures laid down by him is a multifunctional complex which is dissociated into separate activities by thrombin. Other authors believe that his prothrombin preparations are a mixture of proteins, and have supported this belief by resolving the complex, by various procedures, into different components of which the precursor of thrombin is only one. Seegers claims that in these experiments the prothrombin has been modified and no longer represents the native substance.

The individual view of Seegers and his associates is apparent in the chapters devoted to the clinical aspects of coagulation and to immunochemistry, but the book also includes contributions from other authors on topics about which Seegers holds no particular view. There is an excellent review on the fibrinogen fibrin transformation incorporating the latest ideas on the mechanism of fibrin polymerization, and an interesting chapter on the ultrastructure of the fibrin clot. There is also a stimulating discussion on the effect of different surfaces on the proteins involved in blood coagulation.

Other aspects of coagulation which are included are the various inhibitors of blood coagulation, the role of platelets in haemostasis and, finally, a short account of

the chemistry and function of vitamin K.

In spite of these reservations, the student of blood coagulation should find this book useful because it presents an alternative interpretation of the phenomena of clotting, the merits of which can be decided by the reader. M. P. ESNOUF

ANTIBODIES FOR CLOTTING

The Use of Antibodies in the Study of Blood Coagulation By K. W. E. Denson. Pp. ix + 244. (Oxford and Edinburgh: Blackwell Scientific Publications, 1967.) 52s. 6d.

THE mysteries which surround blood coagulation are such as to make the development of a new method for its study an important event. In recent years the addition of techniques of protein chemistry, particularly electrophoresis and ultracentrifugation, to the long-established

coagulation methods has provided new information about the physical characteristics of certain clotting factors. The present volume describes a new approach to the study of the coagulation mechanism, through the provision and elaboration of a technique, which may prove a useful addition to those already mentioned.

The work described in this book was originally submitted

as a thesis for a DPhil degree in the University of Oxford and is essentially the application of immunological methods, in the form of the use of antisera to clotting

factors, to the study of blood coagulation.

The book is in two parts. The first part begins with a description of the two modern concepts of blood coagulation, the "cascade" hypothesis and that which envisages prothrombin as the basic factor, and continues with a detailed description of methods for preparing purified coagulation factors and thus their antisera. There follow two chapters on the characterization of the functional activity of the antisera of six clotting factors and one chapter dealing with the immunochemistry of clotting factors and their antisera.

The second part of the book describes, in great detail. the application of the specific antisera to clotting factors to various aspects of the coagulation mechanism and ends with a general discussion, including the author's con-

clusions and suggestions for further studies.

The detail in which the methods and experiments are described and the results presented is impressive and the treatise is obviously the result of a vast amount of detailed and painstaking labour, on which the author is to be congratulated.

This volume will be of greater value to those wishing to apply these techniques and procedures to their own investigations than to those with a more general interest in coagulation, although the summaries and conclusions at the end of most chapters will assist those not immediately concerned with the full experimental details, while the review of the literature is adequate for the needs of the treatise.

The approach described in this treatise has undoubtedly added, and will continue to add, to our knowledge of the coagulation mechanism. While it may help to resolve some of the differences between the "cascade" hypothesis, founded as it is on investigation of defects in the haemostatic mechanism, and that based on prothrombin, it remains to be seen whether its application will enable new light to be thrown on the all-important and pressing problem of hypercoagulability and thromboembolic disease.

G. B. D. Scott

IMMUNOLOGICAL EXPLOSION

Advances in Immunology

Edited by F. J. Dixon, jun., and J. H. Humphrey. Vol. 6. Pp. xvii+571. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967) 148s.

This volume contains a varied selection of topics. Many of the articles, however, have the common feature that they report results which appear to be just opening the way to the most productive phases of study. For example, P. G. H. Gelland A. Kelus in their article on anti-antibodies devote two pages to idiotypic antibodies. This is a most remarkable phenomenon first observed independently several years ago by Oudin and by the authors, and the far-reaching theoretical implications have aroused such interest that a fuller discussion will be needed very soon. Again the in vitro stimulation of a primary response has been sought for many years and much of Dutton's review is taken up with discussion of unsuccessful or ancillary studies related to this basic problem. The most convincing demonstration that a primary stimulation in vitro was possible, by Mishell and Dutton, must have been made while this review was in preparation and of necessity gets

only brief mention. As a further example the capacity of animals to synthesize antibodies which could distinguish between different types of nucleic acid was in doubt until several years ago. Among other reasons, the close similarity of structure of nucleic acids of different species made it uncertain that an effective antibody response could be obtained. In 1964, Plescia and colleagues (authors of the present article) found that complexing with methylated bovine serum albumin was sufficient to make many nucleic acids effective antigens. Very recently, work at Cambridge has led to the development of methods for solving the chemical structure of RNA. This should make possible detailed correlation of specificity and structure and it opens up many possibilities for the use of specific antiserum in both biochemical and chemical studies in this field. Yet again, the long article by A. E. Gabrielson and R. A. Good on the chemical suppression of adoptive immunity is concluded by a few pages on anti-lymphocyte serum. Although the mechanisms are not understood, this technique may well be the most effective method of suppressing undesirable immune responses and the volume of recently published work on this topic will clearly necessitate a full review very soon.

It is inevitable that with a subject progressing at the present explosive pace of immunology, many reviews will be outdated rapidly, but this does not reduce their value. The exhaustive discussion by Dutton, for example, of in vitro studies of the immunological response includes several long tabulated summaries of much often partially successful work and is not easy to read, but it will remain a valuable guide to the literature for many years to come.

In a less popular area, P. Lachman has reviewed the biochemical (or should it be molecular?) aspects of conglutinin and immunoconglutinin. The former is a high molecular weight globulin found in the serum of cows and several closely related species and structurally has nothing in common with immunoconglutinin which is an immunoglobulin, mainly IgM but also present in the IgG fraction. Both the conglutinins combine with a component or components of complement after the latter's reaction with the antibody—antigen complex, and thus give rise to the characteristic reaction named conglutination. Rapid progress in defining the complement system has made it possible to investigate in more detail the secondary conglutination reaction and the progress achieved is discussed in this article.

A transatlantic collaboration between Sterzl and Silverstein has led to an interesting review of developmental aspects of immunity in which emphasis has been placed on the cellular changes occurring at the onset of immunity in immature animals and when an immune response is initiated in the adult. Immunopathology finds a place in the discussion of experimental glomerulonephritis by Unanue and Dixon, thus completing the wide range of topics reviewed in this volume. Although no doubt it would be profitable, few immunologists will wish to read this issue from cover to cover, but all will find that more than half the articles will be of interest and value to them.

R. R. PORTER

ONE PHYLOGENETIC SYSTEM

Phylo-genetic Systematics.

By Willi Hennig. Translated by D. Dwight Davis and Rainer Zangerl. Pp. 263. (Urbana, Ill., and London: University of Illinois Press, 1966.) 93s.

Although this book has a certain importance as an attempt to think out how far one can derive a phylogenetic arrangement of species from imperfect material—especially from groups with no or only a fragmentary fossil record—it cannot be described as successful. The publishers' blurb describes it as "far in advance of the thinking of most systematic zoologists". Considering

that it is published in the United States, whence some of the best thinking on evolution, phylogeny, taxonomy and metataxonomy has come in recent years, this is a truly remarkable statement, unsupported by the book. It is a strange fact that, with the exception of Timoféeff-Ressovsky until recently, there have been few workers of wide repute on population genetics and evolutionary genetics in Germany, so that the basic processes of evolution have been neglected there for years. outstanding exception of Rensch, there have been very few workers on higher evolutionary processes, while the best-known palaeontologist is probably Schindewolf, whose ideas of typogenesis are rightly rejected by Hennig. Germany, in the past century almost too avant-garde in evolutionary studies, has for many years been undistinguished in this field; yet phylogenetic systematics cannot flourish without a sound knowledge of evolution.

The book is a translation of a complete revision, not available in print, of a previous book, so that the accuracy of translation cannot be checked. Much is hard reading, with obscurity of logical connexion between sentences, a flat and poor style, and frequent repetition of stylistic clichés. One perfect example of how not to put German into English is Ziehen's definition of order, which is given as "the totality of progressively graduated vicinal similarities of more or less determined positional relationships of several or many, even an infinite number, maximally all, 'somethings' within a finite or infinite whole". Yes! And the reader is left to struggle without any help towards elucidating the meanings of the terms. The reader is treated pretty cavalierly throughout; casual statements are made on important matters with no references or only an author's name without further data, although the reader needs to be able to check the author's assertions; legends for text-figures often fail to explain major features of the diagrams; proof-reading and checking are careless (for example, Fig. 66 refers to the Lepidoptera, not merely the butterflies; in Fig. 39, 3 and 5 should be transposed; Vertigo genesii is not a "parasitic snail larva", as the title of the reference quoted makes clear); and important discussions and statements of fact may appear not where they should logically be but in summaries—for example, that on sterility and crossability as means of defining biospecies. The author has the irritating habit of giving very short quotations from a large number of authors with no indication of context, a few words here or a phrase there which have struck him. Where so much divergence of terminology or emphasis exists, this is extremely dangerous, and the critical reader is left with the feeling that he ought to check every short quotation to make sure that the quoted author really meant it in the way that Hennig takes it. One at least certainly did not.

Hennig appears to define the species from an evolutionary point of view as a segment of a phyletic line bounded by two acts of speciation—the piece between two branchings. He firmly rejects the view held by nearly every other worker that if considerable transformation has taken place along this piece, it should not be all included in the same species, and justifies this remarkable procedure by the equally remarkable reason that because profoundly different stages in the life-history are included in the same species, morphology is not a criterion of the species. He dismisses the agamospecies as exceptional, and roundly asserts that no definite case of a species arising by hybridization is known in zoology. Neither statement seems judicious to me, and the title of the book and the treatment of the subject throughout scarcely justify a complete neglect of plants. He appears to believe that closeness of morphological similarity within a group means that the forms in it have diverged only recently-"We placed the fourteen species of the Acrania in one family because relatively little time seems to have passed (as may be inferred, in the absence of other indications, from the minor degree of their morphological divergence) since the existence of their last common stem

form". On present evolutionary and genetical theory this is at best very unsafe, and should be supported by numerous examples from actual fossil records before being accepted even tentatively. He discusses convergences and parallelisms briefly and unsatisfactorily, and assumes as an "auxiliary principle" that the origin of convergence of a character in two forms should never be assumed but always proved. This is done because of his conviction that "phylogenetic systematics would lose all the ground on which it stands" if such characters were always considered as convergences or parallelisms with proof to the contrary required in each case. It is difficult to understand how such a confusion of thought can go unrecognized. In the first place, there is no simple opposition between counting all such characters as showing parallelisms unless there is proof for any to the contrary, and on the contrary counting them all as indicative of common ancestry unless there is evidence otherwise. There is also the very usual position in which we simply do not know what their significance is and would be wholly unjustified in coming to any conclusion. And in the second place, the aim of phylogenetic systematics is surely to produce an arrangement of known forms in as close accord with their sequence of evolution as possible; this so-called "auxiliary" or "heuristic" principle is, in fact, a prejudgment of the very results we are trying to discover. This is no doubt why Tuxen disagreed with Hennig on this point, but he is merely dismissed by Hennig as having "probably misunderstood my heuristic principles". When the results of a science are produced by the methodological assumptions rather than by the evidence available, it is not a science; and in this particular example, it is clear that phylogenetic systematics of this sort should lose the ground on which it stands if it can do no better than this. It is particularly unfortunate that this book should appear at a time of so many attacks on evolutionary studies, systematics and taxonomy by biologists who should know a little more before communicating their ideas so freely; this sort of work gives A. J. CAIN them an easy target.

VERTEBRATES REVISITED

Structure and Habit in Vertebrate Evolution
By G. S. Carter. (Biology Series.) Pp. xiv+520.
(London: Sidgwick and Jackson, 1967.) 63s.

THE aim of Structure and Habit in Vertebrate Evolution is to "relate the structural and biological changes during evolution to changes in the animal's habits of life". It treats in turn the structure and palaeontology of each of the main vertebrate groups and follows this with a general discussion of the significance, in terms of phylogeny, of the changes that have come about at each major advance in vertebrate reorganization.

Some of the points that emerge from this treatment are interesting enough; for example, the adaptation of the respiratory methods, and the structure and physiology of the blood, of amphibian ancestors to a freshwater and then a terrestrial habitat. Throughout, the circulatory system receives fuller and more functional treatment than in most comparable books.

In correlating structure with habit the author is more interested in stressing the possible habits open to vertebrates as a result of some pre-adaptation of structure than in inquiring into the habits that might have selected structures. Thus he is more interesting on the structure and function of accessory respiratory organs and the evolutionary possibilities they provided than on the selective reasons for homothermy or the mammal jaw articulation.

The palaeontology of the vertebrate groups is given a good summary treatment with up to date fossil evidence, but the tentativeness of the approach to important phylogenetic connexions becomes exasperating when it is

applied to every group. Admittedly, it is by no means clear whether arthrodires are ancestral or closely related to the chondrichthyes or the docodonts to the monotremes, but the non-committal attitude to the possible relationships is carried to an extreme that blurs the main evolutionary events and spoils the stated aim of the book which is to study the major changes in vertebrate evolution.

The book should appeal to the student because points of difference between groups are numbered and listed, but this can also confuse where, for instance, the characters of fossil mammals and mammal-like reptiles are dogmatically contrasted in a numbered table and on the next page modified. There are, finally, a number of curious misprints for which there is no excuse—what are microtuberculates?

WILMA GEORGE

INSECTS BY THE MILLION

Insect Colonization and Mass Production Edited by Carroll N. Smith. Pp. xxi+618. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 216s.

THE interested layman as well as scientists in other disciplines must often wonder at the paradox of some entomologists trying to eradicate insect pests and others trying to grow them in the laboratory. This book may provide an answer, for, while it is important to control or eradicate harmful insects, the work is facilitated by knowledge about the life cycle, physiology and behaviour of the insects in controlled laboratory conditions, as well as in the field. Scientists are beginning to realize that successful colonization of insects and other arthropods is essential for efficient and productive research into virtually every aspect of entomology, including control and eradication. For example, a method developed by American entomologists during the Second World War, for rearing human body lice in large numbers on rabbits, led to the development of excellent and rapid techniques for insecticide testing and louse control.

The problem of resistance to insecticides which has assumed serious proportions recently, and its genetical basis, are best studied in laboratory colonies of insects in controlled conditions. Resistance has also highlighted other methods of control, for example biological control using insect parasites, predators and pathogens. All these require the mass production of the host insects on which the parasite, predator or pathogen could be reared in large numbers for release in the field. Recent work on insect attractants has provided information which suggests that insects or products derived from them can be used for the control of a variety of species. In some cases, these attractants have been synthesized, but in others, as in the case of the pink boll worm moth—a serious pest of cotton plants—the only source of the sex attractant at present is reared pink boll worm moths.

Considerable success has been achieved recently in the control and eradication of the screw worm, a serious pest of domestic stock, by releasing in the field mass produced sterilized males. This method of control is now being investigated for the control of various agricultural insect pests and disease carrying arthropods.

Many vital questions of vector host relationships in insects which transmit animal and plant diseases can best be answered through carefully controlled laboratory studies with laboratory grown insects. All these points provide justification for the laboratory colonization and mass production of economically important arthropods.

The five sections in this book deal with colonization of animal parasites and bloodfeeding arthropods (186 pages); insects of domestic and stored products (68 pages); plant feeding insects and mites (214 pages); insect parasites, predators and pathogens (42 pages); and the mass production of insects for the sterile release technique (67 pages).

The various groups of arthropods in each section are dealt with by authorities competent in their particular fields.

It is obviously impossible in a book of this size to include methods of colonization of all the economically important arthropods. The establishment of small laboratory colonies of insects such as rat fleas, Culex pipiens mosquitoes, bed bugs and cone nosed bugs, adequate for normal experimental procedures, is relatively simple and is included in the section on blood sucking insects. I feel, however, that some of this space could have been devoted to phlebotomine sandflies, which are difficult to colonize and which transmit human disease in many parts of the world. The colonization of body lice, biting midges, black flies, stable flies and tsetse flies is justifiably included, because of new successful techniques or because of the inherent difficulties involved. Papers in the Bulletin of the World Health Organization (31, 1964), on culture methods of arthropod vectors and their biological control agents, deal with colonization of some of these groups and of others not covered in the present

The second section, on insects of domestic and stored products, describes methods of rearing and handling house flies, cockroaches, and beetle and moth pests of stored products. The third section is of more interest to the agricultural entomologist and deals with colonization of diverse plant feeding insects and mites such as pine beetles, pink boll worms, cabbage loopers and corn root worms, many of which cause extensive damage to crops.

Perhaps the most interesting sections are the last two, which deal with biological control in one form or another and the colonization and mass production of insect parasites, predators and pathogens such as nuclear polyhedrose viruses of lepidopterous pests. This and the mass production of screw worms, fruit flies and mosquitoes for actual or potential control by release of artificially sterilized males into natural populations have shown the feasibility of using non-chemical methods for controlling insect pests. And this, when so much is heard about actual or potential, real or fancied, hazards of insecticides, is reassuring.

M. G. R. VARMA

TO SPLIT OR NOT TO SPLIT

The Lichen Symbiosis

By Vernon Ahmadjian. (A Blaisdell Book in the Pure and Applied Sciences.) Pp. viii + 152. (Waltham, Mass., and London: Blaisdell Publishing Company, a Division of Ginn and Company, 1967.) \$5.75.

To split a lichen into its two components, an alga and a fungus, and study them separately or to experiment on the complete thallus using radioactive tracers are the two main ways in which the physiology of this symbiosis may be examined. Professor Ahmadjian employs the first technique. The major part of this book gives an excellent account of his researches and those of his colleagues together with the results of earlier workers which are relevant to his approach. There are two chapters at the end of the book on the physiology of the complete plant and on lichen chemistry.

The book is beautifully produced, with a large number of photographs and drawings, although no scale is given on many of the latter. The drawings and photographs of lichen algae are undoubtedly the best published so far. The text is readable and informative, but there are a number of points which might be queried. In the first place, are heterocysts (page 22) any longer regarded as a method of vegetative multiplication of blue-green algae? Again, on page 31, the author cites the work of Kofler and Bouzon to support the statement that "the percentage spore discharge and germination among many temperate lichens are highest in early spring and fall when the most favourable climatic conditions for these processes

generally occur". As I understand it, the main aim of thes workers was to refute the theory of seasonal spore discharge and to show that discharge and germination wermore closely correlated with micro-climate and localimatic conditions than with time of year. (For example in one year they found that the maximum discharge and germination of *Umbilicaria* spp. spores was in July.)

In discussing lichen algae, Professor Ahmadjian has stated more than once that Trebouxia spp. are rarely if ever, found in the free living state (see, for example page 17 of this book). On page 67 he says, however, "that they do occur in small isolated groups among other algae" If this is the case then it would have been valuable to have a cited reference or further details. In view of the author's scepticism that Trebouxia is ever free living, is is surprising that he quotes work (see page 44) which found that "when pigments were extracted from strainform of T. decolorans and compared with those of a non-sensitive, non-lichenized Trebouxia" the pigments differed quantitatively but not qualitatively. Reference to the original paper shows that the non-lichenized species is given as Trebouxia humicola (Naeg.) Treboux, which is correctly Chlorococcum humicolum (Naeg.) Raben., acommon soil alga, and not a Trebouxia at all^{2,3}.

Except for a few criticisms of the type given above, the book is exceptionally useful; first, because it clearly describes a number of techniques for the culture and attempted resynthesis of the lichen symbiosis; second, because it poses many of the unsolved problems regarding the physiology of lichens; and last, because it contains a very comprehensive list of references. The book with its annotated bibliography gives an excellent survey of the present state of lichen physiology which will be welcomed by students and researchers alike.

GAMBLING MATHEMATICS

The Theory of Gambling and Statistical Logic By Richard A. Epstein. Pp. xiii+492. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.) 80s.

The stated aims of this book are "to dissipate the mystery, myths and misconceptions . . . to overcome the appeal of fallacies . . . and to emphasize the advantages of utilizing objective probability in gambling". In so far as an objective mathematical analysis of gambling games is relevant, the book goes far to achieve its aims. Nevertheless, the author's impressive display of negative expectations is hardly likely to daunt the gambler any more than a documentary on cancer cuts the sale of cigarettes. We are to envisage a race of gamblers who are entirely rational, and "who would rather lose intelligently than win ignorantly". A secondary purpose of the book is to unify and bring together material otherwise to be found only in widely scattered sources.

The title of the book is unfortunate. Only about fifty of its 400 or so pages accord with the usual meaning of the words "theory of gambling", and I must confess to being little wiser concerning "statistical logic" after reading this book than before. In fact, by far the greater part of the text consists of an encyclopaedia of gambling games with their mathematical analyses.

The contents can be divided roughly into five categories (although not followed sequentially in the layout of the work). First (second chapter), the author summarizes the necessary prerequisites in probability, statistics and games theory. Although mostly satisfactory, there are occasional lapses in the mathematical exactitude, some of

which might be disastrous to the unwary reader (for instance, page 33).

The second section (third chapter) states and proves ten theorems constituting the author's theory of gambling. Most of these apply to the situation of repeated identical and independent games in which there are at most three outcomes. The first few theorems are contrived to pour increasing quantities of cold water on the so-called miraculous gambling "systems", while the others concern the probability of gambler's ruin and the chance of achieving a target fortune under various strategies of play. Although of direct relevance to simple gambling situations, the mathematician might understandably prefer the more sophisticated approach to be found, for instance, in Dubins and Savage's How to Gamble if You Must (McGraw-Hill, 1965).

Next comes a detailed and fascinating treatment of the probabilistic properties of coin tossing, dice rolling, card shuffling, and the like. Particular consideration is given to the possibilities of prediction and "cheating". leads directly to the fourth and largest category, being the encyclopaedic array of games mentioned here. These range from elementary games (which are solved completely) to games such as bridge (to which a whole chapter is devoted). While numerical solutions to these latter games are as yet inaccessible, the mathematically inclined addict will find much of interest here. Similar considerations are given to horse racing and stock markets, but the results are, of necessity, somewhat limited.

The excellent final chapter returns to the former theme of the book. It examines the widespread belief in luck and other gamblers' superstitions. It concludes with a general discussion of paranormal phenomena, including extrasensory perception experiments.

Anyone reading this book from cover to cover would be well advised to procure an a priori interest in the details of gambling games. To such, however, this book has an undoubted fascination. There is plenty of light relief in the text, and indeed the whole account is well presented and pleasingly written. The mathematical treatment is straightforward, and is thus accessible to a wide readership. J. B. COPAS

OBITUARIES

Professor E. B. Verney

E. B. VERNEY died on August 19 at the age of 73. After some clinical experience he chose an academic career, and in his early days worked under E. H. Starling and T. R. Elliott, both of whom quickly appreciated his worth. In 1926 he was appointed to the chair of pharmacology at University College, London, and in 1934 he moved to Cambridge, his alma mater, as Sheild reader, and in 1946 as the first Sheild professor of pharmacology. retired in 1961 and spent three years as research professor in Melbourne before returning to Cambridge in 1964. He received recognition in various forms and in many countries. Among other honours, he was elected FRCP in 1928 and FRS in 1936.

Verney had the utmost integrity and always thoroughly briefed himself before speaking on a subject or undertaking an experiment. Consequently his opinions were valued and carried considerable weight, and it was realized that his work was meticulous. He was also a first class surgeon and rarely did one of his complicated demonstrations or experiments fail. Preparations for demonstrations might begin at 6.30-7.00 a.m. in order that all should be perfect and ready by mid-morning, and his experimental preparations were on occasion completed by mid or late afternoon, when he would begin observations. Having worked with Starling and Elliott, he was interested in the cardiovascular system and had mastered the art of making heart-lung-kidney preparations. His first important observations added enormously to our knowledge of the pars nervosa of the pituitary gland, an organ about which there was little definite or accurate knowledge at the time he began. He showed beyond doubt that the pituitary released into the blood stream a substance which restored almost normal function to the isolated kidney. and that in the absence of this substance the urine produced was like that of a patient with diabetes insipidus. He further showed that the active substance could not be adrenaline and that its action was independent of renal innervation. He studied the effect of exercise in dogs, in which he collected urine separately from the two kidneys. and demonstrated that both the innervated and denervated organ responded similarly to a water load by diuresis, inhibition on exercise and then recovery. He went on to show that the antidiuretic effect of exercise depended on its emotional content and that one of the stimuli which brought about release of the pituitary substance was a rise in the osmotic pressure of the plasma passing to the region of the anterior hypothalamus. In other words, he showed conclusively that the pars nervosa contained an antidiuretic hormone which regulated the output of water from the kidney and was in turn regulated by the composition of the plasma reaching the hypothalamus.

Verney was also interested in the causes of renal hypertension and demonstrated in conscious dogs that even a brief bilateral occlusion of the renal arteries can lead to a rise in blood pressure. He also showed that hypertension of renal origin could be induced in almost totally sympathectomized dogs, so that in all probability the active substance must act directly on the blood vessels. Latterly Verney turned his attention to the adrenals and among other things showed that adrenocorticotrophic hormone was more effective in releasing glucocorticoids than aldosterone from the isolated perfused gland.

When he died Verney had ended his days of experimental work, but his advice and judgment were still available. They will be deeply missed, but even more his friends will miss Verney for his own sake.

MARY PICKFORD

Dr W. R. Chapman

DR WILLIAM RONALD CHAPMAN, who died on June 29. graduated from Sheffield in 1922 and gained a PhD in 1927. His working career was mainly in the field of coal preparation, and in this he was one of the world experts. and was co-author with R. A. Mott of one of the standard textbooks on the subject, The Cleaning of Coal. He was engaged in preparing a second edition of this book at the time of his death.

Chapman applied his knowledge in various parts of the world; he acted as consultant to the Kailan Mining Administration in China, where he was taken prisoner of war by the Japanese. During his captivity he turned from the cleaning of coal to the making of bread and the cultivation of yeast for this purpose.

After the war he returned to England and was chief coal preparation engineer to the East Midlands Division of the National Coal Board. He then went as adviser on coal preparation to the Turkish Government, returning to Great Britain as assistant director of research of the National Coal Board Coal Research Establishment. During this period he was given leave of absence for a period to advise the Indian Government on coal preparation. He was also an honorary lecturer in coal preparation and minerals engineering at the University of Birmingham. After leaving the National Coal Board he became a consultant to Messrs. Head Wrightson until the time of his death.

During his long career Chapman published many papers in various journals, and sat on many national and international committees. He was a founder member of the Coal Preparation Society and was its president for two years. He was also a member of the editorial advisory board of Coal Preparation.

University News:

Bradford

DR J. B. Helliwell, at present reader in gas dynamics in the University of Strathelyde, has been appointed to the chair of mathematics in the Board of Studies in Engineering, and Dr G. Brown, at present reader in physics, has been appointed professor of nuclear physics. Professor D. C. Johnson, visiting professor at the university, has been appointed to the chair of industrial technology. Professor H. T. Stamboliev, dean of the Faculty of Technology at the University of Skopje, has been appointed to the visiting chair of chemical engineering for the session 1967–68, and Dr M. Green, a director of Zenith Radio Research Corporation (UK) Ltd, has been appointed visiting professor of physical chemistry for a two year period commencing in October this year.

Dundee

Professor A. R. MITCHELL, formerly reader in applied mathematics in the University of St Andrews, has been appointed to the newly created third chair of mathematics.

Lond

THE title of professor of experimental pathology has been conferred on Dr Lynne Reid in respect of her post at the Institute of Diseases of the Chest.

Ulster

MR ALAN MILTON, vice-principal and acting principal of the University College of Rhodesia, has been appointed professor of education and director of the Education Centre.

Appointments

MR A. S. ASHTON, a director of Esso Petroleum Co Ltd, and Mr H. W. Morris, deputy chairman of ICI Fibres Ltd, have been appointed members of the Shipbuilding Industry Board, which was established under the Shipbuilding Industry Act, 1967.

Announcements

THE Ministry of Agriculture, Fisheries and Food has placed an order with Messrs Ferguson Brothers (Port Glasgow) Ltd for a new fisheries research vessel. The vessel, which will replace the present research vessel, Ernest Holt, is expected to be in service in late 1969.

DR LESLIE MULLINS, head of Kodak's technical services to marketing, delivered the Mehl Honor Lecture at the 1967 Conference of the American Society for Non-Destructive Testing. Dr Mullins, the first British scientist who has been invited to present this lecture, spoke on "The Development of Non-Destructive Testing".

THE Drummond Managing Trustees have awarded Mr A. P. Nandi Majumdar a Drummond Scholarship in nutrition for the year 1967-68. The scholarship will be held at the London School of Hygiene and Tropical Medicine.

Meetings

HEATING and Ventilation for a Human Environment, November 1-2, Institution of Mechanical Engineers (R. S. Glynn, The Institution of Mechanical Engineers, 1 Birdcage Walk, London, SW1).

PSYCHOSOMATIC Disorders, November 10-11, London (Dr A. H. Crisp, c/o Academic Psychiatric Unit, Middlesex Hospital, London, W1).

AIR Navigation Conference, November 14—December 13, Montreal (International Civil Aviation Organization, International Aviation Building, 1080 University Street, Montreal).

ERRATUM. In the communication "Transformation of the Histochemical Profile of Skeletal Muscle by 'Foreign' Innervation", by G. Karpati and W. K. Engel (Nature, 215, 1509; 1967), the two photographs appeared in reverse order, so that Fig. 2 was printed above the legend to Fig. 1 and vice versa.

Erratum. In the communication "Markovian Models of Dialogic Time Patterns", by J. Jaffe, S. Feldstein and L. Cassotta (Nature, 216, 93; 1967), the third sentence following equation (1) should read "One consequence of the model is that the probability of reaching any state j from any state i in exactly n steps is given by the ijth term . . .".

Erratum. In the communication "Electron Thermodynamic Nonequilibrium in p-n Junctions", by M. A. Melehy (Nature, 215, 1251; 1967), equation (7) should read $\alpha = (I/I^*)$, $p_e = (1 + \alpha) \ p_n$. The title of the second column of Table 1 should be p_n (cm⁻³).

CORRESPONDENCE

Origin of Plastids

SIR,—I am prompted to write to you briefly on reading, I think for the third time, in the pages of Nature the statement, this time from your Cell Biology Correspondent (216, 14; 1967), "Ever since the discovery that mitochondria and chloroplasts contain . . . there has been speculation that these organelles evolved from symbiotic bacteria . . ." This is an example of a tendency manifested especially by non-biologists now working in the biological field to imagine that the new methods now being applied to biological problems are providing answers and suggesting hypotheses which the older "classical" biologists have not and could not have conceived. I believe the idea that this speculation is a new one should be killed. The idea that both chloroplasts and mitochondria might be organelles evolved from symbiotic bacteria was very much in the air thirty or forty years ago and precisely for the same reason stated by your correspondent—namely, on account of the genetic continuity of both these organelles; and what is new now is not this speculation but the molecular basis on which it can be made, and this seems to me a trivial distinction. Reference to this speculation can be found for mitochondria on page 19 of the book *Protoplasm*, by W. Seifriz, published in 1936. I cannot for the moment lay my hands on a similar statement for chloroplasts, but I recall that in 1935 I attended the Saturday evening seminars organized for his students by Professor O. F. Curtis at Cornell University, during one of which we discussed the possibility that chloroplasts may be derived from symbiotic bacteria. This discussion had then been a feature of the seminars for several years past. coming to Leeds I found precisely the same speculation being placed before his students by Dr (later Professor) W. H. Pearsall and I have no doubt that the same speculation was rife in almost all botany departments in the world at that time.

This is itself a trivial matter, but it is one example in which less than justice is done to the older workers. I believe it is important to keep in mind that development in science is a continuous process; and that younger workers are well advised to keep a wary eye on what was done by their forebears. As a younger worker I was brought up short in this regard both by Professor G. van Iterson, jun., in Holland, and by Professor I. W. Bailey of Harvard. This is a lesson I have never forgotten.

Yours sincerely,

R. D. Preston

Astbury Department of Biophysics, University of Leeds.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, October 30

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr D. L. Thomas and Mr E. P. G. Wright: "The Impact of the CCITT No. 6 Signalling System on Telecommunications".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 5.30 p.m.-Mr Arthur T. Gill: "Faraday and Photography".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, WC1), at 5.30 p.m.—Dr N. A. Mitchison: "Control of the Immune Response".*

University of London Institute of Education (in the Great Hall, King's College, Strand, London, WC2), at 5.30 p.m.—Professor A. V. Judges: "The Idea of Equality in Education".*

INSTITUTION OF MECHANICAL ENGINEERS, PROCESS ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "The Implications of Going Metric".

Monday, October 30-Wednesday, November 1

Institution of Electrical Engineers (at Savoy Place, London, WC2)
-Conference on "Metering and Apparatus for Modern Electricity Supply Tariffs".

Monday, October 30-Thursday, November 2

INSTITUTE OF WELDING (at 54 Princes Gate, Exhibition Road, London, SW7)—Autumn Meeting on "Welding in Non-Ferritic Materials".

Tuesday, October 31

University of London (at the Institute of Child Health, Guilford Street, London, WC1), at 5.30 p.m.—Dr J. R. Tata: "Hormonal Control of Protein Synthesis". (Fifth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

INSTITUTION OF MECHANICAL ENGINEERS, HYDRAULIC PLANT AND MACHINERY GROUP (at 1 Birdcage Walk, Westminster, London, SWI), at 6 p.m.—Discussion Meeting on "Requirements—How to Specify Them to Advantage".

University of Hull (in the Assembly Hall), at 8 p.m.—Professor M. V. Wilkes, FRS: "Digital Computers from their Early Beginnings to the Present Time" (The St. John's College, Cambridge Lecture).

Wednesday, November I

BOYAL INSTITUTION, HISTORY OF SOIENCE DISCUSSION GROUP (at 21 Albemarle Street, London, W1), at 1 p.m.—Mr Frank Greenaway: "Victorian Attitudes to the Application of Science".

BIOMETRIO SOCIETY, BRITISH REGION (at the Wellcome Building, Euston Road, London, NW1), at 2.30 p.m.—Professor J. F. Scott: "The Investigation of a Psychological Syndrome by Multivariate Analysis"; Mr G. M. Clarke: "Inverse Polynomial Response Surfaces Applied to Data from Plant Nutrition Experiments".

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W1), at 3 p.m.—Symposium on "Triassic Rocks of the British Isles".

University of London (at the Institute of Dental Surgery, Gray's Inn Road, London, WC1), at 5 p.m.—Professor Sir John McMichael: "Science and Practice".*

University of London (at Bedford College, Regent's Park, London, NW1), at 5.15 p.m.—Sir John Wolfenden: "Universities and the State".*

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W1), at 5.30 p.m.—Mr H. P. Munro: "Uses of Critical Path Planning".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Dr A. G. J. MacFarlane: "State Space Methods in Dynamical Systems Analysis".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, TELECOMMUNICATIONS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, WC1), at 6 p.m.—Mr K. E. Martin and Mr B. E. Attwood: "Deflection Circuits for Colour and Monochrome Television Receivers".

Wednesday, November I—Thursday, November 2

INSTITUTION OF MECHANICAL ENGINEERS, THERMODYNAMICS AND FLUID MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, SW1)—Symposium on "Heating and Ventilation for a Human Environment".

Thursday, November 2

ROYAL SOCIETY (at 6 Carlton House, Terrace, London, SW1), at 10 a.m.—Discussion Meeting on "Anomalous Aspects of Biochemistry of Possible Significance in Discussing the Origins and Distribution of Life" organized by Mr N. W. Pirie, FRS.

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 2.30 p.m.—Professor Ronald King: "The Atomic Nucleus and Nuclear Energy" (Civil Service Lecture).

ROYAL SOCIETY OF ARTS, COMMONWEALTH SECTION (at John Adam Street, Adelphi, London, WC2), at 5.15 p.m.—Mr J. R. Stebbing, OBE: "Possible Contributions of Nuclear Science to the Needs of Africa".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Sir Harry Melville, KCB, FRS: "The Position of Fundamental Scientific Research in the United Kingdom" (Third Appleton Lecture).

UNIVERSITY OF LONDON (at the Institute of Child Health, Guilford Street, London, WC1), at 5,30 p.m.—Mr D. P. Burkitt: "Study of Cancer Patterns in Africa". (Sixth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

University of London (in the Physiology Theatre, University College London, Gower Street, London, WC1), at 5.30 p.m.—Dr Britton Chance: "Electron and Ion Transport in Mitochondrial Membranes".*

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (at 14 Belgrave Square, London, SW1), at 6 p.m.—Meeting on "The Biodeterioration of Plastics".

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, SE1), at 6 p.m.—Mr H. W. Miller and Mr T. P. Gordon Brown: "Recent Developments in Ground Freezing".

PHARMACEDTICAL SOCIETY OF GREAT BRITAIN (at 17 Bloomsbury Square, London, WC1), at 7 p.m.—Dr J. G. Dare: "A Brief Survey of Australian Pharmacy".

UNIVERSITY OF LONDON (at Withersdane Hall, Wye College, near Ashford, Kent), at 8.15 p.m.—The Right Hon. Lord Annan: "Where are the Universities Going?"*

Friday, November 3

ROYAL INSTITUTION, PHOTOCHEMISTRY DISCUSSION GROUP (at 21 Albemarie Street, London, W1), at 1 p.m.—Professor D. Bryce-Smith: "Some Recent Developments in the Photochemistry of Benzine".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (joint meeting with the Manchester Section, Agriculture and Food Groups, at the Literary and Philosophical Society's House, 36 George Street, Manchester), at 1.30 p.m.—Symposium on "Food Production in the Year 2,000 A.D.".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 9 p.m.—Professor J. Maynard Smith: "The Genetics of Ageing".

Saturday, November 4

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum. London Road, Forest Hill, London, SE23), at 3.30 p.m.—Mr Richard Tapper: "On Migration with the Shahsavan Tribesmen of Persia".*

Monday, November 6

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 1.15 p.m.-Professor Ronald King: "Faraday—Father of Electrical Engineering".

FARADAY SOCIETY (in the Department of Chemistry, The University, Edinburgh), at 4.30 p.m.—Professor Dudley Herschbach (Harvard University): "Molecular Beam Kinetics" (Bourke Lecture).*

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at $5.30~\rm p.m.$ —Lecture on "AC and DC Current Comparators".

INSTITUTION OF MECHANICAL ENGINEERS, NUCLEAR ENERGY GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "What Can We Do Without in a Nuclear Power Station?"

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT ECTION (at Savoy Place, London, WC2), at 6.30 p.m.—Mr F. F. Mazda: "Thyristor Control".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, SW1), at 6.30 p.m.—Dr M. W. Davles: "The Chemistry of Iron and Steel Making".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

Sentor Demonstrator (with an honours degree in microbiology, extensive experience in the organization and operation of practical courses, and preferably experience in research) in Microbiology at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (London and Brisbane, November 3).

LECTURER of ASSISTANT LECTURER (with interests in fungal physiology or morphogenesis) in Mycology—The Registrar, The University, Leicester (November 4).

LECTURER (with a good honours degree in physics or electronic engineering and relevant teaching and research or industrial experience) in Physics—The Principal, Rutherford College of Technology, Ellison Place, Newcastle upon Tyne, 1 (November 4).

CHAIR OF EXPERIMENTAL PHYSICS—The Secretary (NAT), University of Stirling, Stirling, Scotland (November 6).

SENIOR LECTURER IN PATHOLOGY—The Registrar, The University, Sheffield (November 10).

CHAIR OF CONTROL ENGINEERING in the DEPARTMENT OF ELECTRICAL ENGINEERING—The Registrar, University of Salford, Salford 5, Lancashire (November 14).

JUNIOR LECTURER/LECTURER/SENIOR LECTURER IN HORTICULTURE at Massey University, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (New Zealand and London, November 15).

LECTURER or ASSISTANT LECTURER (preferably with qualifications in parasitology and/or entomology) in Zoology at the University of Botswana, Lesotho and Swaziland—The Inter-University Council, 33 Bedford Place, London, WC1 (November 15).

FARM Demonstrator (with a degree in agriculture or an honours degree in pure science followed by an adequate postgraduate qualification)—The Secretary, School of Agriculture, University of Cambridge, Cambridge (Sambridge (November 18).

Assispant Lecturer or Lecturer in Theoretical Physics or atomic contributions.

Der 18).
ASSISTANT LECTURER OF LECTURER IN THEORETICAL PHYSICS (candidates should have worked in theoretical problems in solid state physics or atomic spectroscopy)—The Registrar (Room 38, O.R.B.), The University, Reading (November 20).
LECTURER (Smallfact in Canada and Cana

(November 20).

LECTURER (qualified in one or more of the following fields: blometry, agricultural statistics, blomathematics, mathematical statistics, an agricultural or biological discipline with supplementary experience in its mathematical or statistical aspects) in BIOMETRY in the DEPARTMENT OF ACRICULTURAL BOTANY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, SWI (Australia and London, November 24).

CHAIR OF PHYSIOAL CHEMISTRY at Massey University, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, SWI (New Zealand and London, November 30).

HEAD (physiologist with a postgraduate qualification) of the Crop Physiology Department in the Botany Division, to study the growth of herbage

. . .

plants with particular reference to the natural environment—The Secretary, Grassland Research Institute, Hurley; Maidenhead, Berkshire (December 1).

READER or SENIOR LECTURER IN MICROBIOLOGY at the University of Tasmania—The Association of Commonwealth, Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (Australia and London, December 4).

IMMUNOLOGIST or BIOCHEMIST (with immunological experience) to collaborate in the development of isotopic methods in the immune assay of

IMMUNOLOGIST OF BIOCHEMIST (with immunological experience) to collaborate in the development of isotopic methods in the immune assay of 'lysosomal enzymes—The Administrative Secretary, Strangeways Research Laboratory, Wort's Causeway, Cambridge.

LECTURER IN BIOCHEMISTRY: a LECTURER IN MICROBIAL GENERICS; a LECTURER IN ZOOLOGY (specializing in physiology); and a LECTURER IN BOTANY—The Principal, Barking Regional College of Technology, Longbridge, Road, Dagenham, Essex.

LECTURER (with a basic knowledge of physics, and preferably research experience in the field of sediment studies on the Continental Shelf, particularly in the geological aspects) in GEOPHYSICS—The Registrar (S), Bath University of Technology, Bath, Somerset, quoting Ref. 67/116.

REESBARCH ASSISTANT (with a first-or second-class degree in some branch of engineering or physics) in the DEPARTMENT OF APPLIED MATTEMATICS for research in rheology—The Registrar, University College of Wales, Aberystwyth.

for research in rheology—The Registrar, University Courge of manes, Aberystwyth.

Technician for work involving the manipulation of radio-active materials, including labelling procedures, and the use of a range of different types of counter—The Secretary, Institute of Nuclear Medicine, Middlesex Hospital Medical School, London, Wi.

Technician (preferably with previous experience in bacteriology or biochemistry) for the Microbiology Section of the Department of Botany, to be responsible for laboratories used both for teaching and research purposes—The Registrar, The University, Nottingham.

NATURE Volume 216 NOVEMBER 4, 1967

Almost a Good Bargain

THE University Grants Committee has done well, in all the circumstances, to negotiate a reasonably generous agreement on the quinquennium starting in 1968. Only a few months ago, it seemed as if there would be all kinds of deprivation in the period immediately ahead. Not merely did it seem as if the economic pressures on the British Government would make it hard actually to provide the money which the universities will need if they are to continue to grow. There was also a period during which it seemed as if the Government was flirting with the notion that a period of stagnation in the universities would do no serious harm. That at least was the impression created by much of the oversanguine talk about the future development of polytechnics which accompanied the first statements about the potential benefits of the binary system now emerging for British higher education. In the event, it seems as if the universities will be able to grow steadily although not exuberantly in the five years ahead. That is something to be glad about.

In terms of the recurrent grant, there will be an increase of 28 per cent in the five years ahead, and an accompanying increase of roughly 22 per cent in the student population, which suggests that the universities should be able fairly comfortably to keep their heads above water. Indeed, this simple comparison may considerably underestimate the strength of the position of the universities, for there is some evidence of slack in the university system as things are at present. There is, for example, scope for making much better use of the skills and energies of university teachers. The expansion of the past five years has also enabled the universities to recruit people to their staffs more quickly than they are able to deploy them in the teaching force. With skill and good housekeeping, the universities as a whole should be able to keep ticking over comfortably in the next quinquennium.

But this is only half the story. Nobody's interest will be served if the universities grow bigger but stay the same in the quinquennium ahead. And by now it is clear for all to see that these five years will see the introduction of a great many innovations in the pattern of university teaching. One consequence is that the universities will—or should—find themselves spending more heavily on new kinds of lecture rooms, new kinds

of ancillary aids to the teaching process and even on new kinds of teaching. This will, and should, be comparatively expensive, which suggests that the comparatively modest grants—£16 million next year rising to £18 million in five years—which the UGC is now being given for equipment and furniture may be the first component of the new budget to show obvious signs of strain. And although there is obviously no point in fighting battles before they are engaged, the universities would do well to make early preparations for a thorough study of the ways in which educational innovations may change the character of university teaching and the scale of their demands on the public purse.

The other side of this coin is that the quinquennium ahead should see important steps towards a much more economical use of the capital equipment now locked up in the universities. It is now several years since it became possible to talk safely, in university common rooms, of schemes for adding an extra term to the university year, for example, or for making changes in the ratio of teachers to undergraduates which has had the status of a magic number (one to nine for undergraduates and one to three for postgraduates) ever since the Robbins Committee reported. So far, however, talk has tended to become a substitute for change. There is, however, good reason to believe that moderate reforms along these and other lines could bring important economies and greater freedom for the universities as a whole. It would also help towards the same objectives if the universities were to take more vigorous steps towards regional planning among themselves. Britain is now so thickly sprinkled with universities that the attempt to create from scratch virtually identical educational establishments in cities separated by thirty miles or so is often extravagant and sometimes absurd. But there is also a case for asking that the universities collectively should somehow encourage a greater diversity among themselves. The attempts of the UGC to push towards this worthy objective have not been markedly successful, which is not much of a surprise. The universities themselves could win great benefits by this means, however, and this is something which they ought to work towards in the quinquennium now ahead.

Who Should Keep the Books?

So the British Government has decided not to build a new British Museum Library, or any other, at Bloomsbury. Instead, it intends to go back to square one and to think quickly about the functions a national library should fulfil and the best means of achieving them with existing libraries. Although the way the Government announced this decision is deplorable, the decision itself may well prove to be right. That entirely depends on what sort of national library is eventually created, where it is built, and whether or

 $\mathcal{M}_{\mathcal{A}} \neq \emptyset$

not the Government's action becomes a cause for still further delay.

Unfortunately it is not possible to regard the Government action simply as a belated recognition that it could do a more thorough job in the forward planning of British libraries. Mr Gordon Walker seems to have reached his decision in a manner almost calculated to insult the trustees of the British Museum. It is true that most of them have been long in public life, and have developed broad backs as a result, but is it really wise that the Department of Education and Science should show such little respect to its voluntary servants? Is it sensible to allow distinguished men to work away at plans for a new library for the best part of two decades, only to tell them just before contracts are to be let that there is no building to be done? It is entirely possible that the proposed building in Bloomsbury would have done more architectural damage to the neighbourhood than sensible men would like to see, and there are all kinds of other grounds on which the plans could have been argued against. But the department's failure properly to consult the trustees is not merely discourteous but potentially dangerous how easy will it be for the minister to recruit advisers in the months ahead?

That said, it was entirely sensible that the Government should ask-before it became inextricably committed to building the proposed new British Museum Library—whether simple rehousing of the museum library would be the best way to provide a national library service. Under the existing plan, the British Museum Library would simply have moved into a bigger building. It was never planned as a national library-indeed, the trustees have always been careful never to refer to it as such. But the report of the UGC committee under Dr Thomas Parry made it clear that it is the only institution which could hope to fulfil even part of that role. Under the same plan, the National Reference Library for Science and Invention-essentially the stock of the Patent Office Library with additions from the British Museum-was formally instituted in 1966 and placed under the British Museum. This was to have been housed separately on a site on the South Bank of the Thames, near Waterloo Bridge. That, however, has at last gone the way of all Cheshire cats.

So, with the Government not committed to any site or building, the committee which it is to set up will at least have a chance to propose a radical reorganization to plan for a complete national library service. The two most important decisions to be made are whether or not the national library should comprise several broadly specialized units separately housed or one comprehensive library and whether these should be autonomous, administered in part or wholly by the British Museum.

The recent tendency has been to separate libraries by subject—the National Reference Library for Science and Invention and the National Lending Library for Science and Technology are indicative—and the UGC Committee on Libraries proposed similar national

lending and reference libraries for social sciences and the humanities. But the case for giving up separation by subject and building a single great comprehensive national reference library is strong. First, as recent events prove, the more sites that have to be found and buildings planned, the less the chances of any actually being started. Second, a multiplicity of buildings will inevitably create duplication of some facilities. Third, the boundaries between disciplines are already obscure and bound to become more so; any division based on subject is bound to lead to anomalies and overlap. Fourth, it is not obvious why it should be easier to co-ordinate the activities of several units when they are scattered about London rather than under one roof, or why a single library if properly organized is less able to deal with the enormous growth of literature in all subjects. The Parry report is hard to follow on this point.

Whether or not the decision is for a single comprehensive library or for two or three broadly specialized libraries, it is vital that they should be organized to make the greatest use of computers for cataloguing, data processing and retrieval. The use of computers in libraries is still in its infancy, but twenty years from now it is hard to see how these tasks can be accomplished any other way. The British Museum Library is investigating the possibility of automatic data processing to maintain its catalogue and automate as many library functions as possible. The National Reference Library for Science and Invention and the British Museum Library use different cataloguing systems, and the only hope of co-ordinating these lies in the development of a computerized catalogue. But can this easily be achieved within the existing framework of the British Museum? There is at least a case for thinking it would be better to set up a new body, independent of the British Museum, to organize and run the national library—even if this did mean that the traditional links between the British Museum and its library were broken. But even if in the end the Government decides to leave the relationship between the museum and its library much as it is, the National Reference Library for Science and Invention should be separately administered by an organization which understands the needs and problems of science, technology and industry. There is no reason why some outside body such as the Royal Society should not be persuaded to do this. If Mr Gordon Walker's abruptness was really a sign that the Government had at last recognized that placing the National Reference Library for Science and Invention under the British Museum was a mistake, he may yet win back some supporters.

In parallel with the national library, which must obviously be a reference library, there is a need for a comprehensive system of national lending libraries. The National Lending Library for Science and Technology, established by the Department of Education and Science in 1962, has been operating successfully from Boston Spa in Yorkshire and could serve as a model for two new national lending libraries for the social sciences and humanities which should not of

course be built in London. Why not have all three at Boston Spa co-ordinated as the National Lending Library, and providing a focal point for all the lending library services in the country? At the moment the resources of the National Central Library in London, which is severely limited by lack of money, are pitifully inadequate to meet a mounting demand for lending material in these fields, and as a result the National Lending Library for Science and Technology has already started to collect social sciences periodicals.

But where should all these buildings be? The Government may regret the decision to abandon the Bloomsbury site. It has thrown away a unique opportunity of having the national library and the great national collection of antiquities side by side, which could only have increased the efficient use of both. Although a national library has more important functions than providing research libraries for the departments of the British Museum, these would not have been impeded by having the two institutions on one site.

Bloomsbury Cinderella

THE Secretary of State for Education and Science, Mr Patrick Gordon Walker, brought consternation to the trustees of the British Museum, and to a good many other people as well, by his announcement on October 26 that the British Government has decided not to proceed with the scheme for building an extension to the British Museum in Bloomsbury put forward in detailed form a year ago. That scheme would have entailed the development, on a site opposite the frontage of the present museum, of a new building to hold the overflow from the library of the museum, now bursting at the seams. In his statement in the House of Commons, Mr Gordon Walker gave as his principal reason for rejecting the development scheme, on which the trustees of the museum have been working for the best part of two decades, the view that the Camden Borough Council is right to protest at the destruction of the 500 dwellings that would have to be knocked down before the new library could be built. But it is plain that Mr Gordon Walker has also welcomed this opportunity to take another look at the development of central library services in Britain, which is why he has decided to set up an independent committee to give advice on the development of central libraries.

The committee will particularly concern itself with the question of the storage needs of the libraries.

The trustees of the British Museum have reacted strongly to this announcement, and the chairman, Lord Radcliffe, has denied Mr Gordon Walker's suggestion that he had been consulted in advance. The independent committee has not yet been appointed, but the minister has promised that it will report within twelve months. This further review comes at a time when the trustees of the museum are seeking to appoint a new director in succession to Sir Frank Francis, who is retiring this year, which may have suggested to the Government that the time is ripe for a further examination of the relationship between the library and the other collections of the British Museum. The issue is particularly important to scientists because the National Reference Library for Science and Invention is a dependant of the British Museum, and has not yet

But did the Government feel that the autonomy of a national library would be jeopardized if it were too close to the British Museum? It must have realized that by refusing to develop Bloomsbury it was creating enormous difficulties for itself. Mr Gordon Walker confidently asserts that a new site can be found in time for building to begin on schedule in the early 1970s. It must. There have been too many delays already, and providing national library facilities is a matter of utmost urgency. The cost of delays rises steadily. Merely hiring storage space will cost the British Museum alone an average of more than half a million pounds annually between now and 1985, when the planned library was to have been completed. The cost to the nation caused by the inefficient use of libraries because of overcrowded and totally inadequate facilities is incalculable. If the Government is to dispel the scepticism and despair that fill both library users and keepers, it must live up to its promise that its committee will reach a decision within twelve months.

been provided with a site on which to unite its two divisions, one at the Patent Office Library and one in Queensway.

Money for Dons

MR PATRICK GORDON WALKER last week announced how much money would be made available to the British universities over the next five years. The figures show a less dramatic increase than has been customary over the last five years, but there are several reasons for this. The major period of expansion after the report of the Robbins Committee is now over, for one thing, and expansion in the next five years is likely to be less swift. For another, the provision made for equipment has now been listed as a separate item, in line with the new equipment grants which have caused so much rancour between universities and the UGC.

As the table shows, the equipment grants will begin in 1968-69. The recurrent grant for this year was flad million

The Secretary of State also announced that a further £1.65 million would be made available this year for the purchase of furniture and equipment. This extra grant will go some way towards filling the gap between what the universities wanted and what the UGC has so far been able to supply. The UGC says that it will be increasing rations to some selected universities. The number of students in British universities is now running ahead of the Robbins predictions; this year the number will probably exceed 200,000, against the Robbins target of 197,000. By 1971–72, the Robbins Committee estimated the total university population at 204,000, but the grants announced last week assume that the totals will in fact have risen to between 220,000 and 225,000 by that date.

	RECURRENT	EQUIPMENT		
	GRANTS	GRANTS		
1967-68	£150-8 million			
196869	£153·6 ,,	£16.5 million		
1969–70	£159·5 "	£19·0 ,,		
197071	£166·0 ,,	£18·25 "		
1971–72	£172·5 ,,	£18·25 "		

The grants will not be allocated to the individual universities until approximately November 18; Vice-Chancellors generally consider therefore that it is too early to decide whether or not they are adequate. Dr C. L. Bosanquet of Newcastle University considers that the proposals are at first sight reasonably encouraging and Dr D. G. Christopherson of Durham University welcomes the £1.65 million allocated to the purchase of university furniture and equipment for the current financial year. Each university is aware of its own needs but is ignorant of the needs of others and it may be some time therefore before an overall picture of the national situation is built up.

Money for Schools

Grants to students cost local authorities just over £58 million in 1965–66. The vast majority of the expenditure was made up by the full value awards, which cover fees and a maintenance element subject to parental income. There were 167,547 of these awards in 1965–66, and they cost £56 million. The other £2 million is made up by a further 21,000 lesser value awards, made by local authorities either for non-scheduled courses, or to students who do not qualify academically for a full award.

The figures are given in the latest bulletin of statistics from the Department of Education and Science, Statistics of Education, Volume 5 (HMSO, 8s 6d). The volume covers finance and awards, and shows that at the end of 1966 a total of £124 million had been approved for building schools and colleges of education.

Science for Primary Schools

This week the Nuffield Foundation brought out four books and three pamphlets in the Nuffield Junior Science Project, intended for teachers in primary schools. All are published by William Collins Sons and Co. Ltd. and they mark an important new development in Nuffield Science teaching.

The Nuffield approach of learning by doing is particularly suitable for primary schools, which have shown themselves more willing than most to abandon the traditional approaches to teaching. The books and booklets just published are intended to give the primary school teacher both a general idea of what Nuffield teaching means and practical examples which have been proved in the classrooms. One of the books is devoted to apparatus, and contains some remarkable examples made by children of average ability at an urban primary school. They include quite elaborate electrical circuits, including a buzzer working on a simple "make and break" circuit which went through no less than four development stages before reaching a Development of the buzzers brought final model. both miniaturization and increasing efficiency, and the final model incorporated three electromagnets and a threaded adjustor to control the amount of vibration.

The other books in the series describe the work which can be done with animal and plants in the classroom, and two guides for teachers with examples of projects which were done by classes in the early stage of the project. One of the three booklets describes how the changing seasons can be used to stimulate children's interest in science, and the other two describe experiments with mammals in the classroom, and, perhaps

oddly, how science and history can be taught simultaneously. The introduction puts history firmly in its place—"Many people have been taught to regard history as consisting almost exclusively of politics... if history is to make sense to children, they must surely be encouraged to put themselves in the position of the men who made the discoveries which contributed to our present understanding of the world."

Whether the Nuffield Junior Science Project will redress this supposed imbalance remains to be seen. Its own fault is its tendency to elevate curiosity to the status of discovery.

Causes of Death

TEN years ago the World Health Organization produced a study of cardiovascular diseases and resulting mortality in twenty-four countries. Following the observation of low death rates from these diseases in Latin America, a further study was begun with the intention of providing a comprehensive account of the causes of mortality of adults in widely separated populations. The final results of the survey have just been published by the Pan American Health Organization.

Eleven cities with annual death rates of about 2,000 and efficient death registration systems were selected for study. A twelfth, Ribeirão Prêto, with only 500–600 deaths per year, was included because of the high incidence of Chagas infection. The cities, each an established medical centre, were Bogotá and Cali (Colombia), Carácas (Venezuela), Guatemala City (Guatemala), La Plata (Argentina), Lima (Peru), Mexico City (Mexico), Ribeirão Prêto and São Paulo (Brazil) and Santiago (Chile). Bristol and San Francisco were included for comparison. The aim was to investigate 2,000 deaths in each city for each of two consecutive years, by means of a standard questionnaire.

In Latin American countries birth rates and child mortality rates are high, and death rates must be adjusted to take this into account. Up to the mid-forty age group mortality rates in Latin American cities are double those of Bristol, while in the rural areas of South America they are probably about three times the Bristol level. Thus in Guatemala the mortality rate of young adults is six times that in Britain (Bristol figures being close to the national average). Cities in South America are more favourable than the country, but the reverse is true in San Francisco. For the 35–54 age group, death rates for the city are above the national average.

Two diseases emerge as leading causes of death. Diseases of the heart were the leading cause for males in eight cities, and for females in three. Cancer led in three cities for men and in nine cities for women. Cirrhosis of the liver, chiefly caused by alcohol, caused most male deaths in Santiago. Chagas disease was responsible for a large number of deaths in Ribeirão Prêto but did not appear significantly in any other city. La Plata had the highest number of deaths from cancer for both sexes; Bristol, not far behind, had the same number of male lung cancer victims. The figure for male cancer deaths in Mexico City was about half that for the other cities, but the reason is not known. This city had the highest death rate from diabetes mellitus. In the respiratory diseases, death from bronchitis was

particularly common in Bristol. Motor accidents caused a significant number of all the deaths from external sources.

The survey concludes with possible numbers of deaths which could have been prevented. Males are more likely than females to die from alcoholism and external causes, and over half the deaths for men under 35 are thought to be preventable. For women under 35 the figure is just about half. In the 35–54 age group these figures fall to around 40 per cent for both sexes and in the 55–74 group they fall again to 20–30 per cent. A significant number of female deaths are attributable to pregnancy and childbirth, and, of these, abortions form a substantial, and preventable part. The situation in country districts of South America, where shortage of medical facilities is thought to be responsible for the high mortality rates of young adults, is one which can be changed.

Less Discrimination

RACIAL discrimination in Britain was described in a report sponsored by PEP (Political and Economic Planning) and published in April this year. Further legislation was thought to be necessary and the Race Relations Board has now sponsored a complementary report which would be a guide for Government action in extending the 1965 Race Relations Act. Professor Harry Street, Mr Geoffrey Howe and Mr Geoffrey Bindman have made a thorough investigation of anti-discrimination legislation in countries other than Britain, assessed its effectiveness and considered what types of legislation would be most suitable for Britain. Their findings (Anti-Discrimination Legislation, The Street Report) are published this week by PEP.

Much has been learned from legislation in the United States on discrimination which has often been too little and too late. To prevent inequality becoming entrenched in British society, the Street Report proposes widespread extension of the present act to cover all aspects of public life and a large proportion of private tracts, insurance and all services from shops and repairs to those of professional people should, it says, be added to the present list of public buildings, trans-Crown and government port and entertainment. employment should be included except where national security questions have to be considered. Small units of housing or employment where family relationships are involved are the only cases recommended as exceptions to the law. Owner occupied houses are thought to be such a fundamental part of family life that legislation against discrimination in sales of such properties is thought to be a political question, and the report, without a unanimous decision, hands the matter to the Government.

Discrimination on factors of race, colour and ethnic or national origin is the basis of the legislation, but religious discrimination should not be included. It is emphasized that legislation alone will not be enough. Wholehearted government backing must be given to ensure that the law is enforced efficiently, and that justice is seen to be done. Education programmes are essential to show the public the importance of an integrated society. The report suggests that the structure of the Race Relations Board and its local conciliation committees should be strengthened to put

these proposals into effect, and the powers of the board should be extended. The board should be able to issue subpoenas, but their orders should only be enforceable through the courts. Conciliation is the key word in discrimination proceedings, but a tribunal should be set up for cases where it fails. There should be no question of criminal penalties for unlawful discrimination, but failure to comply with decisions could result in proceedings for contempt of court.

Heat and Sound

PROFESSOR EIGEN, who shares the Nobel Prize for Chemistry, has worked closely in collaboration with L. deMaeyer at Gottingen and has introduced and developed a technique for following the kinetics of very rapid reactions in solution and has worked on both the theory and practice of reactions ranging from 0·1 sec, down to almost the limit of chemical reactions.

The principal difficulty in studying fast reactions is bringing the reactants together in a sufficiently short time. That is, the mixing time must be less than the reaction time. Professor Eigen's solution is to take a system in equilibrium and to subject it to a disturbance in the external parameter such as temperature, pressure or electric field strength. changes the position of the equilibrium but sometimes the position is not readjusted as soon as the external conditions have been changed: that is, there is a The displacement from equilibrium is time lag. measured spectrophotometrically or by conductivity. It is a first order process and the reciprocal of the rate constant is the relaxation time. The latter is a composite function of the rate constants of the elementary steps occurring in the reacting system. By analysing chemical relaxation (the difference between "internal" and "external" conditions) under different conditions, intimate details of chemical reactions in the system can be studied.

There are two particular techniques. is a stationary method of analysis using, for example. ultrasonics: the second is a transient method using temperature jump. The latter is the more versatile and best developed but it does not measure the fastest techniques. Chemical relaxation is important because it has opened up a vast new range of chemical reactions for kinetic studies. It was originally used for very fast inorganic studies such as proton transfer and metal complex formation in water. In the last few years, however, attention has been focused on reactions of biological importance; for example, enzyme-substrate reactions, muscle contraction and protein synthesis. It can also be used to follow DNA replication reactions—one base pair replication of DNA must occur at least every 10-3 sec. Eigen's main interest now lies in this biophysical field and he is to have the use of a new Max-Planck institute which will be opened in three years.

Flashing Lights

THE award of a half-share in the Nobel Prize for Chemistry to Professors R. G. W. Norrish and George Porter is reckoned to be a fitting recognition of twenty years of careful work by two talented experimenters. Professor Norrish retired two years ago as professor of physical chemistry at Cambridge, but remains actively

at work at the laboratories. Professor Porter was a research student at Cambridge after the Second World War, and it was there that he and Professor Norrish began work on the development of flash photolysis as a technique for the study of extremely fast chemical reactions, usually by the intermediary of unstable molecular species. In 1955 he moved to Sheffield as professor of chemistry and then, a year ago, to the Royal Institution as director.

It is probably fair to say that Nobel Prizes are of two kinds-those awarded for discoveries of an immediate character, and those awarded for the opening up of a new field of investigation, which usually entails the development of a new technique. This is a Nobel Prize of the second kind, and is in this sense comparable to the award of Nobel Prizes in the past for the development of techniques such as the use of photographic emulsions for the measurement of cosmic rays and the study of nuclear reactions or for the application of X-ray diffraction analysis to the definition of tertiary structure in proteins. Not merely is flash photolysis as such a difficult technique, but its full value is only realizable now that there is a sufficient body of information available for the interpretation of results to be fairly straightforward and unambiguous. What Professors Norrish and Porter have done may well be described as the founding of a novel kind of chemistry.

Over the years, the duration of the pulses of light energy used for the irradiation of a sample of material has decreased from a millisecond to a microsecond, and the arrival of lasers has made it likely that there will now be a further compression of the time-scale. At the same time, energy output has steadily increased, with the result that 1,000 Joules may be fed through a light source in one pulse and that chemistry laboratories are made to seem even more like thermonuclear research establishments, with banks of capacitors accumulating charge. Perhaps the most tangible benefit so far is that it is now possible to observe directly the properties of some of the unstable molecular species which are assumed to play a part in chemical reactions. Now that Professor Porter has turned his interest to the study of flash photolysis in liquids and solutions, the harvest of innovation will no doubt be even more diverse.

Nuclear Reactions

Professor Hans Bethe, who is awarded the Nobel Prize for Physics for 1967, is one of the most productive of Grand Old Men. He has been a prolific source of innovation in theoretical physics since the early thirties, and although the Nobel Committee has singled out for special mention his identification (in 1938) of the nuclear reactions most probably responsible for the output of stellar energy, this represents only a very small part of his output.

Professor Bethe, who is 61, left Germany for the United States in 1935, and was by then distinguished for his versatility. His review articles on the theory of metals and of nuclear reactions—the latter published in 1937—are models of their kind (and still topical enough to be re-edited and republished). His first pieces of theoretical physics were concerned with the motion of electrons in solids, and were carried out in collaboration with Professor A. Sommerfeld. In the

early thirties he made a monumental contribution (with Heitler) by calculating the electrodynamics of electron-positron pair production. His contributions to nuclear physics proper began in 1934 with some calculations of nucleon-nucleon scattering, and by 1936 he was deeply involved in the scattering of nuclear particles from multi-nucleon nuclei. Bethe was one of the first to make calculations with the meson field as a means of mediating nuclear interactions.

Bethe's paper on the thermonuclear energy of stars may seem almost to be a by-product of the remainder of his activity. By the late thirties, the problem was to identify which nuclear reactions could realistically be supposed to contribute to the energy production in Bethe picked out two possible sequences of reactions by which hydrogen may be converted into helium—that which involves the successive additions of protons to a proton to form helium-3 followed by the interaction of two helium-3 nuclei to form one of helium-4, and that which involves a shuttling of protons between the isotopes of carbon and nitrogen. At the time it seemed as if the carbon-nitrogen cycle would be the chief source of thermonuclear energy in stars. Now it is more probable that the direct sequence of events is the more important.

Bethe has been a public figure as well as a physicist. After his stint at Los Alamos, he returned to Cornell University and has since been unafraid to involve himself in the Oppenheimer hearing (where, it is true, he had no option) and in public discussion about such issues as the feasibility of technical methods of disarmament—the detection of underground explosions, for example.

Striking a Balance

SCIENCE and technology have not yet swept the board in the schools with innovations of the curriculum. Members of the Group for Educational Services in Museums have now launched a service designed to bring young people to a closer understanding of their place in history.

The service will function in several ways. First, it will provide facilities for teachers and students to make use of collections in museums. These will cover art, geography, history and natural history. Second, it will organize regular loan distribution of museum objects for schools. Finally, the service will organize miscellaneous activities such as lectures and clubs. Two patterns of organization are in operation. One is based on county boroughs or borough museums administered by a committee of the authority and financed by grants from the local education authorities. The other, the county service, may or may not be based on a county museum, but is financed chiefly or wholly by the county education committee. Sometimes a service may also have an advisory committee consisting of teachers or schools inspectors. All the services are in the charge of a school officer who is responsible to the chief officer of the museum or education committee for detailed administration of the departments.

Organization will depend to a large extent on the particular area. Thus rural areas will have a greater need of a loan service than will better equipped urban areas, and the cost will be higher. The character of an area will also be reflected in the line of study: for

example, near the coast studies may be expected to be predominantly marine. The size of area covered by one service will vary, but there is inevitably an optimum above which it will be necessary to modify the sims of a service to produce maximum efficiency.

The scheme is already established in three places—Bristol, Leicester and Derbyshire. Staff will be expected to have the usual teaching qualifications but in addition may have to study for the Museums Association diploma. Teachers who question the necessity of the scheme are reminded by the Museum Group that the experience gained by a child in becoming directly acquainted with an object is the chief justification for the time and money spent. The group is particularly emphatic in its belief that museum collections can help children to see their environment in a clearer perspective of time.

Traffic in Towns

PROFESSOR R. J. SMEED, first occupant of the new chair of traffic studies at University College London, took the opportunity in his inaugural address last week to describe the academic and practical merits of his young subject. About 8 per cent of all male deaths occur on the roads, and 16 per cent of the national income is spent on road transport. The problems are worth investigating. By discussing one aspect of the subject, traffic congestion in town centres, Professor Smeed was able to illustrate his point.

Formulae have been devised to relate the variables of traffic movement, so that calculations can be made of such things as speeds, journey times, and road space requirements. As traffic increases, each extra car adds more congestion than the last. Under light traffic conditions a one mile journey could take 2.7 minutes, while at 50 per cent of maximum traffic the same journey could take 3.7 minutes and at 98 per cent of the maximum it could take 20 minutes. There is, however, a limit to congestion, because people will not spend more than a certain amount of time in a traffic jam, but will change their transport, work or home to avoid Motorways would increase traffic flow more efficiently than an equivalent ordinary road, and better junctions would give dramatic increases in town road capacity. Ring roads improve the conditions inside towns, but produce intersection difficulties and lengthen journey distances. An average bus carries the equivalent of six car loads, but sending all commuters by bus instead of allowing cars would only improve the journey time of the original bus users, not those of everyone.

The problem of congestion is a simple one—too many vehicles—but the most obvious suggestion of more road space would not solve it, because more people would immediately take to their cars and return the congestion to its former levels. Since the amount of traffic in Britain is likely to double in the next 10-20 years, the road capacity to get traffic moving fast would have to be vastly increased. It is calculated that capacity required in London would be 20 times its present level, an unlikely amount, even with redesigned vehicles which will travel closer together. Congestion seems to be the inevitable result of car-owning commuters. The only cure at present suggested is to remove people, home, work and all, to less crowded places, or else charge them prohibitive amounts for entering any central zone.

Kind Words for Concrete

THE annual report of the Cement and Concrete Association for 1966 makes one point clear—in the association's opinion, too few concrete roads are being built. Mr L. Russell, director-general of the association, points out that concrete is not necessarily more expensive than other forms of construction, even at first cost. Improvement in design and the use of modern equipment has made concrete fully competitive even without taking into account subsequent maintenance costs, as has been demonstrated by a number of recent Apart from direct cost comparisons, every motorist is aware that maintenance and repair work cannot be carried out without serious congestion and great risk of accident. It is becoming essential to place greater emphasis on lower maintenance characteristics in future road construction—and the association believes that the concrete road is immeasurably superior in this respect.

The Lofthouse report had suggested that the ministry might need to revise its present conceptions about the balance between different types of road construction and it considered that the maximum benefit would not be achieved if the proportion of concrete paving remained as small as it had been in recent years. The association looks to the ministry to ensure that concrete is given the opportunity to compete on level terms for all future road construction contracts.

In the report Mr Russell draws attention to developments in the field of skid resistance of concrete roads, in which the association has been collaborating closely with the Road Research Laboratory during the past three years. The type of texture required to achieve maximum skid resistance at high speeds has been established and also the best method of imparting the texture during construction. Tests have shown that, if properly applied, the texture will last for at least ten to fifteen years, after which economical methods of restoring the texture are available.

Fewer Locusts

DURING 1966 the Anti-Locust Research Centre expanded its activities, and because of continued recession in locust activity was able to turn its attention to other pests and a larger number of projects This follows the policy decided by the overseas. Advisory Committee on Anti-Locust Research at its 1965 meeting, with the accompanying proviso that at first pests should be studied to which anti-locust methods could be applied. The Ministry of Overseas Development appointed an Overseas Pest Control Research Committee to replace the Tropical Pesticides Research Committee and, by giving it wider terms of reference, put the ALRC under its wing. As a result the advisory committee, in operation since 1946. was no longer necessary and its activities were wound up in October 1966.

The annual report of the centre which has just been published (HMSO, 7s.) describes the position and frequency of nine species of locusts and grasshoppers. Research work at the centre covers various fields, ranging from taxonomy and insecticides to biogeographical analyses of locust occurrence and the application of meteorology to locust problems. Biological research included the setting up of cultures

of two agricultural pests other than locusts, these being cotton stainer (*Dysdercus intermedius*) and the army worm species *Prodenia litura*. Four new species of Orthoptera were also added to the cultures. Morphometry, behaviour and maturation studies of locusts were continued, together with the physiology of feeding receptors. Chemical attractants in grasses were studied in collaboration with the Tropical Products Institute.

During the year the field research section was working in three continents, and the ALRC continued to increase its international co-operation. Four long-term projects were initiated, studying various aspects of locust populations in the Niger Republic, Saudi Arabia and Australia, and investigating the army worm in eastern Africa. Records for the desert locust were brought up to date by the publication of a further 522 reports. Annual expenditure for the centre during 1966 was £150,000.

Australian Fisheries

Tuna tagging is not the only pursuit of the CSIRO Division of Fisheries and Oceanography. According to two important schemes initiated this year, laboratories are to be constructed, one in Western Australia and one in Queensland, to house teams engaged in co-operative research programmes. Each will be financed by the government concerned. The Western Australian laboratory will be built at Perth to study in particular the physiology and behaviour of crayfish. The Queensland government has agreed to build a laboratory near Brisbane and the research team will undertake a general study of the biology of the main prawn species in southern Queensland waters. As in the case of the Western Australian crayfish, physiological and ecological research will be aimed at improving techniques of study of natural populations and to investigate possibilities of resource manipulation.

Several other research programmes sponsored by the division are in progress. For example, an atlas is being prepared of water conditions around Australia using nearly 20,000 observations of surface temperature and salinity. Work has continued on the processing and interpretation of accumulated data on tuna and Australian salmon, and data are being collected on the development and distribution of species of crayfish, prawns and bottom organisms. An investigation of the occurrence of sperm whales off Western Australia has shown that there has been an overall decrease of between 20 and 40 per cent since 1962. Five cruises were made by oceanographers during the year and deep sea investigations in conjunction with onshore laboratory studies of various aspects of oceanographic methodology were continued. New work in biochemistry, hydrology physics and physical chemistry was undertaken to supplement existing information and the amount of dissolved organic matter produced by phytoplankton during photosynthesis was measured during a cruise in the eastern Indian Ocean in June

The division received assistance from many sources during the year: ships collected oceanographic information, fishermen tagged fish and canneries provided information on tuna, salmon and crayfish measurements.

Parliament in Britain

Cervical Cytology

SINCE 1964 the rate at which cervical cytology smears are being examined has increased by a factor of three. Mr Julian Snow, Parliamentary Secretary at the Ministry of Health, gave the figures in reply to a question in the House of Commons. In June 1967 the laboratories responsible for examining smears were doing so at the rate of 19,000 a year. Mr Kenneth Robinson, Minister of Health, said that he was considering the possibility of extending the service to women under 35. (Written answer, October 23.)

Medical Schools

MRS SHIRLEY WILLIAMS, Minister of State at the Department of Education and Science, confirmed that a new medical school would be established at the University of Southampton. When this and other projects were complete, the number of places for medical students in the United Kingdom would have been increased by 650, she said. (Written answer, October 23.)

Concord

No further increases in the cost of the Concord supersonic airliner were admitted by Mr John Stonehouse, Minister of State at the Ministry of Technology, when he answered a question on October 24. The cost would be £500 million at 1966 prices, and another £100 million might be needed in the seventies to cover costs in advance of receipts. Will Concord make a profit? Mr Stonehouse was not to be drawn—"The return on Government expenditure on Concord will depend on the success in selling the aircraft." (Written answer, October 24.)

Aldabra

No decision has yet been made whether or not to use the island of Aldabra for defence purposes. This was virtually the only hard fact which emerged from the reply by Mr Merlyn Rees, Under Secretary of State for Defence for the Royal Air Force, to an adjournment debate opened by Mr Tam Dalyell. Mr Dalyell had started by suggesting that a Select Committee on Defence should be established to examine questions like these, and that the first witness should be Sir Solly Zuckerman. Mr Dalyell doubted the figure of £20 million which had been quoted as the cost of establishing a base on Aldabra—he thought the cost could well be as much as £100 million by the end of the day. The Royal Society, he said, was convinced that any development of Aldabra would inevitably destroy the greater part of its unique biological features. In any case, he doubted the strategic necessity for the base, or the staging post, whichever it was to be.

Mr Rees replied briefly, without committing the Government to an attitude towards the island. But he did admit that a number of other islands had been considered—Farquhar, the Cosmoledos, Assumption, Astove, St. Pierre, Mahé and so on. Mr Rees said that it had been decided that it would be possible to make a change to the East Channel without damming it, and this, he hoped, would lessen the effect on the ecology of the island if Aldabra were indeed selected. He refused to comment on the suggestion that it would be necessary to build a wall around the airfield to keep out the giant tortoises. As for the frigate birds, the hazard they present to aircraft would be one of the things considered before a decision was reached.

NEWS AND VIEWS

Artificial Intelligence

THE Science Research Council has done well to make a grant of £221,000 to the Department of Machine Intelligence and Perception at the University of Edinburgh to support the work now planned there for the next five years. For one thing, it is imaginative of the council to have backed so generously a group of talented people who have chosen to band together to work in a new and difficult field, often in the process turning their backs on comfortable and established reputations in other fields. It is also potentially a great benefit that on this occasion the Science Research Council should have been prepared to support the rapid growth of what cannot fail to be a commanding centre of excellence, as the phrase now goes, at least for several years ahead. It is true, of course, that the University of Edinburgh will be the first university in Britain to be equipped with a multiple-access computer, and that such a device is almost as important to those who work in artificial intelligence as is a radio-telescope to radioastronomers, but considerations like these are notand have not always been in the past-sufficient reasons for avoiding a wasteful dispersal of resources. (It is worth asking, in passing, when some other British university will have access to a multiple-access computer.) But the most important cause for pleasure with what the Science Research Council has done is that the field on which the group at Edinburgh is embarked has the most exciting promise. Enough has already been done at other British laboratories—the National Physical Laboratory, for example—to demonstrate the great interest of attempts to use computers for tasks other than wooden and repetitive arithmetic. In the United States there has been quite a boom in artificial intelligence for some years now. A good deal of what is spent on these activities is justified by their potential practical importance, in applications such as character recognition, for example. More immediately, however, there is the real prospect that everybody will be stimulated and improved by work of the kind now being undertaken.

Variable X-ray Star

THERE has been wide interest this week in the discovery of a markedly variable X-ray star in rocket flights from Woomera in Australia. According to newspaper reports, Professor K. G. McCracken of the University of Adelaide and Dr A. G. Fenton of the University of Tasmania have announced the disappearance of an X-ray star which was a bright object of its kind when first discovered earlier this year. Three separate groups have been concerned with the description of the event. By means of launchings of Skylark rockets from Woomera on April 4 and April 20 last year, the Australian group was able to single out the existence of a bright source of X-rays in Centaurus (declination 60° south, right ascension 13 hours 20 minutes). A British rocket flight from Woomera on April 10 seems to have taken place by good luck more or less at the peak of X-ray activity. By the end of May, when an American rocket was launched from Hawaii, however, the intensity of the X-ray source had fallen by a factor of six. Now, it seems, there has been a further reduction by a factor of ten.

The importance of this discovery lies in the unmistakable character of the variation of X-ray output from the star. Hitherto it has been hard to ensure that measured variations of output from X-ray stars could accurately be attributed to inherent variation. Friedman's group at the US Naval Research Laboratory has, however, reported a fourfold decrease of the intensity of the Cygnus source called R1 in a period of just over a year, and there are other reports of similar variability in other stars. Friedman and his colleagues suggest, for example, that this source and that known as XR2 are both markedly variable, with periods of the order of a month. So far, however, it has not been possible unambiguously to follow the earlier X-ray stars through a complete cycle of variation. Friedman and

his colleagues follow Shklovsky in the view that many X-ray sources may be double star systems in which a compact neutron star is the chief source of radiation and in which there is an eclipsing star which can periodically interrupt the passage of X-rays. Elsewhere—as among the group associated with the British experiments at the University of Leicester—the theory that X-ray stars are novae has firm supporters.

More News from Venus

THERE is now some confusion about the interpretation of the reports that the Russian spacecraft Venus IV demonstrated the absence of nitrogen from the atmosphere of the planet. In Moscow on October 30, Academician Keldysch described some of the preliminary results of the experiment, and confirmed that the devices with which the spacecraft was provided for the analysis of atmospheric gases on Venus included analysers for carbon dioxide, water, oxygen and nitrogen. He did not, however, confirm earlier reports that nitrogen was found to be entirely absent. It also became plain that the atmosphere of Venus was sampled at two points only, at heights corresponding to pressures of 520 mm and 1,500 mm. The pressure at the surface of the planet was estimated to be within 2 atmospheres of 20 atmospheres, and the pressure is still one atmosphere at a height of 26 kilometres. In the circumstances, it will not be surprising if the lower layers of the atmosphere of Venus are eventually found to have a somewhat different composition from that now measured directly.

Measurements of water and oxygen in the atmospheric gases were carried out with simple absorbers of phosphorus pentoxide and phosphorus, respectively. The accuracy of the carbon dioxide measurement is

given as ten per cent. The concentration of oxygen appears to have been within 0.4 and 0.8 per cent, and the total of water vapour and oxygen was given as 1.5 per cent. At the levels in the atmosphere at which these analyses were carried out, the temperatures were comparatively high-40° C at 520 mm and 80° C at 1.500 mm.

According to Academician Keldysch, there is no doubt that the Russian spacecraft actually reached the surface of Venus. Heights above the surface were determined by means of radio altimeters, probably at a speed (calculated from the Doppler shift) of three metres per second. At various stages during the descent, the deceleration of the instrument capsule was as great as 300g. According to the same account by Professor Keldysch, there is no ionosphere worth talking of on Venus—the concentration of positive ions never exceeded 1,000 particles per cubic centimetre. magnetic field, measured with a directional magnetometer, is less than three ten thousandths of the dipole magnetic field of the Earth. It also appears that the spacecraft used a resistance thermometer for the measurement of temperature and an aneroid barometer for the measurement of pressure.

Automatic Pipettes

A "Which" type of investigation has been used to assess thirty-five automatic dispensing pipettes that are at present available in Britain. Results of the assessment—carried out by Mr P. M. G. Broughton of the University of Leeds, Mr A. H. Gowenlock of the University of Manchester, Mr G. M. Widdowson of the Queen Elizabeth Hospital, Birmingham, and Mr K. A. Ahlquist of the Christie Hospital and Holt Radium Institute, Manchester-appear in the third scientific report of the Association of Clinical Biochemists. Each instrument was tested in at least one of four laboratories and its ease and speed of use, accuracy and precision were assessed.

The instruments tested were of two types, those with a fixed volume determined by the manufacturer and those with an adjustable volume. Instruments were further divided into four groups. Group A included instruments based on a pipette, group \vec{B} consisted of syringe pipettes, group \vec{C} contained double action pipettes and group D contained electrically operated automatic pipettes. Instruments based on a pipette were found to be fragile and the rate of delivery was no faster than with conventional glass pipettes. Syringe pipettes, on the other hand, are said to be faster, more adaptable and more accurate than conventional ones, but many were fragile, expensive and difficult to use. Double action pipettes were fairly fast and usually precise but some were fragile and expensive. Electrically operated pipettes in group D were considerably more expensive and seemed best suited to mechanized or semi-automatic mechanized systems.

Of the thirty-five instruments, nine had faults when received or developed faults during use. Only six were considered sufficiently precise and easy to use. These were the "Zipette", "Quickfit Dispenser", Schuco Automatic Pipette (adjustable model), "Autospenser", "Volusence" and "Auto-Dispenser". Prices were, respectively: £4 9s. 6d. (10 ml. size), £6 15s. (10 ml.), £13 (10 ml.), £25 (5 ml.), £34 7s. (10 ml.) and £36 (10 ml.). In view of these unsatisfactory results, it is

hardly surprising that only three instruments were specifically guaranteed by the manufacturers.

Russian View of Phylogeny

by Mary Lindley

Professor A. L. Takhtajan of the Komarov Botanical Institute of the USSR Academy of Sciences was formally admitted a foreign member of the Linnean Society at the meeting on October 26. Professor Takhtajan, a distinguished taxonomist, then delivered a communication on classification and phylogeny with

special reference to the flowering plants.

He began by putting systematics in its place at the centre of biology; it is not an auxiliary discipline devoted to producing a catalogue of living organisms, but a synthetic science capable of drawing all biological knowledge into an ordered system. Considering classification, Professor Takhtajan said that there are two types—general purpose and special purpose—and only the former is needed today. To be useful, a general purpose classification must convey as much information as possible about the organisms it classifies. Because the phyletic system can convey so much information about the flowering plants and their relationships, upon which it depends, this system will be much more valuable than any others.

In a group lke the flowering plants, with such an inadequate fossil record, a complete phylogeny such as there is for man and the horse cannot be possible. This is α-taxonomy, when the fossil record shows clearly what evolutionary changes were involved in the development of contemporary species. (Professor Takhtajan was not optimistic about the suggestion that a useful ancient angiosperm might be found in Lower Cretaceous deposits.) Phylogenetic relationships, however, can be worked out within taxa, based on the relative primitiveness and advancement of the plants concerned. This a-taxonomy, based on information from comparative morphology, cytology, seriology and now to some extent on DNA hybridization studies, reveals horizontal relationships between members of groups. From these horizontal relationships it may be possible to deduce vertical relationships so that hypothetical lineages can be constructed. As more botanical knowledge is made available more of these relationships will be revealed.

Professor Takhtajan discussed some of the problems involved in finding phylogenetic relationships. Parallelism and convergence may have allowed common characters to evolve in distantly related organisms; in the first case from similar origins, and in the second case from different origins, both as a result of adaptation to similar environmental conditions. should not cause much difficulty as long as there are sufficient independent characters. Another problem arises when a taxon contains members with characters at different stages of evolution, because different characters have evolved at different rates or have reverted to a more primitive condition. This phenomenon, called heterobatmy by Professor Takhtajan, is expressed to a greater extent in primitive taxa such as the Magnoliaceae and Winteraceae. In such cases it is usually impossible to produce a phyletic series. In spite of these difficulties, Professor Takhtajan feels that as more botanical knowledge becomes available—only comparatively few groups have been studied sufficiently

yet—an α -phylogeny will be possible for the flowering plants.

Commonwealth Veterinary Association

from a Correspondent

REPRESENTATIVES from Gambia, Ghana, India, Kenya, Lesotho, Malta, Malaysia, Nigeria, Pakistan and Uganda were able to attend the 85th Congress of the British Veterinary Association held at Southport during the week commencing September 17, thanks to grants from the Commonwealth Foundation. These representatives met others from Australia, Canada, Malawi, New Zealand and the United Kingdom. Sir Dawda Jawara, Prime Minister of the Gambia, and himself a veterinary surgeon, chaired six meetings held during congress week, at which the possible formation of a Commonwealth Veterinary Association was discussed.

All the delegates were in favour of establishing the association, particularly in view of the world shortage of protein. In 1962, the Food and Agriculture Organization estimated that in the United Kingdom, the United States and France alone some £1,500,000,000 worth of food was destroyed as a result of animal disease. That was 15 per cent of the total production of food. In the less developed countries the figure rose to something like 30 per cent. It was felt that reducing this loss might be even more important to mankind than the direct work on human health, and all delegates agreed that the veterinary profession could help, through the Commonwealth Foundation, in improving human health and nutrition both by a direct contribution to food production and by the control of zoonotic diseases

As a result of the six meetings held during the week, a draft constitution was agreed unanimously. Two of its aims are to promote the closest possible links between member associations within the Commonwealth and to facilitate the dissemination of professional and scientific knowledge and information. The representatives of the sixteen countries agreed to recommend the draft constitution to all Commonwealth countries, including those not represented at Southport. They agreed also that a Commonwealth Veterinary Association should be set up as soon as possible, and that it should have a permanent central secretariat established in a Commonwealth member country.

Whatever the future of a Commonwealth Veterinary Association may be, there can be no doubt that the current series of meetings were pervaded by the spirit of goodwill and co-operation which has been characteristic of Commonwealth meetings and did much to increase the understanding of problems of animal health and disease throughout the Commonwealth.

New Place for Plants

from a Correspondent

Two new plant houses at the Royal Botanic Garden, Edinburgh, were officially opened by HRH Princess Margaret on Wednesday, October 25. The buildings, designed by the Ministry of Public Building and Works, have a unique structure with no internal framework. The glass is suspended from an intricate external array of steel tubes and cable. The design frees the interior

from any supporting framework and minimizes the corrosion risk that is common to ferrous metals in plant houses.

The scheme, which cost £263,000, consists of a new exhibition plant house and an exhibition orchid house. The plant house, 420 ft. by 60 ft., is divided by glass screens into five compartments. Each has a different environment with temperature controlled by fully automatic heating and ventilating equipment. The different sections will be occupied by cacti and succulent plants, warm temperate aquatic plants, temperate plants, tropical aquatic plants, and temperate ferns. Planting has been designed to achieve a natural landscaping effect, and wherever possible has a geo-graphical basis. The plant collections are intended to give as representative a picture as possible of the groups concerned, and will be supplemented with specimens of botanical interest collected by staff on expeditions abroad. An observation window, built below water level in the tropical aquatic plant pool, allows visitors to study the underwater parts of plants. The orchid house, 100 ft. by 50 ft., connects with the main new exhibition house and the existing palm house. The new buildings replace dilapidated glasshouses that were built at the beginning of the century. The temperate palm house and the 140-year-old tropical palm house are being renovated and retained.

The Royal Botanic Garden, Edinburgh, founded in 1670, is now a department of the Ministry of Public Building and Works. It covers 75 acres and is visited annually by more than half a million people. Research in the taxonomy of both flowering and non-flowering plants is the primary task of the institution. Studies in the laboratory at present include cytotaxonomy, anatomy, palynology, developmental morphology and various aspects of the experimental taxonomy of fungi.

Localization of Enzymes

from our Cell Biology Correspondent

Analyses of isolated cell organelles have shown that the intracellular distribution of many enzymes is very restricted. Indeed, the enzyme content of organelles is so characteristic that the presence of a particular enzyme is often used as a marker during the isolation of them. How is such precise localization of enzymes determined? Does it arise simply because of the structure of the enzyme molecule or are there specific localizing factors? In 1961, Paigen discovered that a mutation in the structural gene of β glucuronidase, an enzyme which is localized in lysosomes and the endoplasmic reticulum in mouse liver cells, alters the distribution of the enzyme between the two sites.

It is not therefore surprising that the structure of an enzyme can affect its intracellular localization, but this is not the complete explanation. Ganschow and Paigen ($Proc.\ US\ Nat.\ Acad.\ Sci., 58, 938; 1967$) have now discovered a nuclear gene which controls the localization of β glucuronidase in the endoplasmic reticulum. They find that in liver cells of mice, strain YBR, glucuronidase is present in the lysosomes but not in the microsomes (isolated endoplasmic reticulum) and, as far as they could tell, this was the only significant difference between YBR microsomes and those of other strains. A series of genetic crosses and back

crosses with YBR and another strain CH3/HeHa proved that the structural gene of glucuronidase in YBR was not mutated and showed that YBR lacks a specific factor essential for the insertion of the enzyme into the endoplasmic reticulum. This factor is also required for the insertion of glucuronidase in C3H/HeHa and the gene which specifies it, the E gene, is in a different linkage group to the glucuronidase structural gene.

This is the first proof that a nuclear gene can specifically regulate the intracellular localization of an enzyme. This factor could work either by altering the structure of native glucuronidase so that it can fit into the reticulum or, more probably, by providing a specific binding site for the enzyme; it may even be a structural component of the reticulum membrane. If so, the implication is that other enzymes associated with the reticulum are localized by similar nuclear genes and the localization of enzymes in other organelles may also be genetically controlled. Certainly this would explain the highly specific distributions found in practice.

In mitochondria, where the correct assembly of enzymes is critical for co-ordinated function, Woodward and Munkres (1966) found evidence that the precise conformation of malic dehydrogenase, which is specified by a nuclear gene, is determined by interaction with mitochondrial structural protein, which is specified by the organelles DNA. Specification of enzyme binding sites could be one of the major functions of plastid DNA, whereas in organelles which do not contain DNA this could be effected by nuclear genes like the E gene discovered by Ganschow and Paigen.

Plant Virus in Vectors

from our Microbiology Correspondent

Since 1960 several research groups have demonstrated by electron microscopy the presence of insect-borne plant viruses within their insect vectors. Dr Karl Maramorosch and his colleagues Hirumi and Granados have concentrated their efforts on the wound tumour virus (WTV) and studied its distribution and multiplication in leafhoppers. The location of WTV in a relatively efficient vector, Agallia constricta, and in an inefficient vector, Agalliopsis novella, is described in two recent publications (J. Virol., 1, 430; 1967; and J. Invert. Pathol., 9, 147; 1967), and the observations made are related to the transmitting efficiencies of the leafhoppers. In the inefficient vector, wound tumour virions were distributed systemically in the midgut, musculature, blood, fat bodies, tracheoblasts and ventral ganglia. This is the first direct evidence of plant viruses invading the nervous tissues of insect vectors and corroborates the earlier antigenic analyses of Sinha (Virology, 26, 673; 1965). However, Sinha's experiments did not distinguish between complete viruses, sub-viral constituents and soluble viral anti-

The accumulation of WTV in all organs of A. novella was slight and, significantly, the low titre or complete absence of virions in the salivary glands suggests an immediate reason why this species is a poor vector for this virus. Although systemic infection of these leafhoppers by WTV is clearly indicated, the establishment of a disease condition has not been verified. The authors rightly point out that the killing of

occasional vectors could easily be missed and suggest that it is improbable that such systemic viraemia could remain completely harmless. Invasion of the insect nervous system was examined fully in A. constricta, the more efficient transmitter of the disease. Three types of viral formation occurred in nervous tissues: isolated virions (V₁) found predominantly in the ganglion cells; tubular formations (V2) in which single files of virions lie within membranous envelopes; and aggregate formations (V3) bounded by limiting membranes. These latter inclusion bodies were distributed mainly in the glial cells, perineurium and tracheo-blasts. Wound tumour virus produces an intense cytopathogenic effect on nerve cells and, most notably, the cytoplasm of degenerating ganglion cells was converted into an electron dense matrix containing fibrous material and ribosomes. These matrix areas surrounded by WTV particles closely resemble those in situ aggregations of pox-viruses, reo-viruses and polio-viruses which are thought to represent centres of virus synthesis. A reasonable inference from the present study is that the V₁-type virions associated with polysomes are early stages of virus development and that the dense matrix areas indicate active sites of WTV multiplication. In contrast, the V₃-aggregations which are rarely associated with the matrix areas or polysomes are considered to denote virus storage. significance of the tubular symmetry in virus development is not known. They have been detected before in non-nervous tissues of the vectors and in host plants while similar structures are common to other insectborne plant virus systems. Maramorosch's group are at present using leafhopper culture cells to pursue this problem further and their future reports will be awaited with interest.

Hydroxyproline in Cell Walls

from a Correspondent in Cell Biology

Hydroxyproline, an imino-acid which is found in only a few proteins such as animal collagen, also occurs in a protein of plant cell walls. This protein, sometimes called extensin, is linked to the cellulose microfibrils of the wall. One of its properties is to increase the tensile strength of the wall but it also seems to be associated with cell growth. Free hydroxyproline inhibits cell growth at 1 mM, and even does so in the presence of indole acetic acid (IAA)—a plant hormone, which greatly stimulates cell enlargement. A great deal of work published this year attempts to pin-point the site of hydroxyproline inhibition in the hope that this will give a clue to the mechanism of cell growth regulation.

IAA is thought to enhance cell growth through the stimulation of RNA and protein synthesis. Cleland (Plant Physiol., 42, 1165; 1967), using oat seedling coleoptiles, has shown that free hydroxyproline does not affect these two processes. Instead, he proposes that hydroxyproline blocks the utilization of a particular protein rich in hydroxyproline, possibly by feedback inhibition, needed for wall growth. Earlier, Cleland had shown (Plant Physiol., 42, 271; 1967) that the effect of hydroxyproline, on growth stimulated by IAA is not immediate. This suggests that a pool of this protein is present and is used up before inhibition takes place. Experiments with cycloheximide and p-fluorophenylalanine suggest that the protein is being synthes-

ized in cells capable of enlargement even before they are stimulated to greater enlargement by IAA. However, hydroxyproline had no effect on the subsequent ability of the cells to enlarge.

There may be a further mechanism of hydroxyproline inhibition. Using sycamore callus tissue, Holleman (Proc. US Nat. Acad. Sci., 57, 50; 1967) showed that the hydroxyproline in the wall protein arose from hydroxylation of previously incorporated proline (as in collagen). In the presence of an inhibitor of hydroxylation (aa'-dipyridyl) hydroxyproline added to the cells was still incorporated into the cell wall protein. Holleman suggests that this incorporated hydroxyproline has forced its way into the protein which is then rendered non-functional, and in this way causes the cell growth inhibition. But what is the function of this protein? Although it is implicated with cell enlargement, Cleland and Karlsnes (*Plant Physiol.*, 42, 669; 1967) also implicate it with the cessation of enlargement. Their conclusion is based on the finding that in cell walls of growing pea epicotyls, the greatest increase in the protein which contains hydroxyproline occurs when cell elongation has finished. The two systems may not be incompatible but certainly there are no clear-cut answers yet. More data are needed on the types of protein required for cell growth and on the mechanism by which IAA influences these, and also how this hydroxyproline-containing protein fits into the cell wall during enlargement.

This protein, extensin, has often been likened to collagen and indeed collagen has now been reported by De and Ghosh (*Exp. Cell Res.*, 47, 637; 1967) to be present in plant cells. But surprisingly it is in the nucleus.

Sulphur in RNA

from our Molecular Biology Correspondent

The discovery of sulphydryl groups in transfer RNA has increased the number and variety of "unusual" bases recognized in these species. Their function, though the subject of some slightly remote speculation, is unknown. The very unexpectedness of the thiolated bases and their chemical reactivity, which offers the possibility of generating covalent cross-links, makes them, however, a source of considerable interest.

There appear to be several such bases, but one of them, 4-thiouracil, is the most prevalent. In total tRNA from E. coli there appear to be rather fewer than two sulphur atoms per molecule. Lipsett has now shown (J. Biol. Chem., 242, 4067; 1967) that, as expected, mild oxidation converts the thiol groups into disulphide bonds, and from a complete nuclease digest of tRNA a 4-thioUMP disulphide has been isolated. No mixed disulphides with any other thiolated nucleotides are found. In a further study Lipsett and Doctor (ibid., 4072) have examined a single tRNA, with a greater than average thiol content. This is E. coli tyrosine tRNA—one of the easier species to prepare, since it appears at one end of the countercurrent distribution profile. Titrations with thiol reagents show that two sulphydryl groups are present, and both turn out to be 4-thioUMP. On reduction, a disulphide bridge is formed as before, and it is surprising to find that the sedimentation coefficient is not increased. It follows that the disulphide bridge is intramolecular. This is a useful (as well as an unexpected)

result, for it indicates that none of the dimeric, and other aggregated, species which have been observed by other workers are likely to involve intermolecular disulphide bonds.

This internal disulphide formation is accompanied by a small but significant increase in absorbance and a decrease in thermal stability. It therefore seems likely that the new bond is achieved at the expense of some base-pairing. At the same time the amino-acid acceptor activity survives intact, despite the evident disturbance of the conformation. (It has not so far been established whether other functions, such as the capacity to attach to the ribosome, are extirpated).

The 4-thioUMP has an absorption band at about 330 m μ , which is therefore resolved from the main nucleotide absorption centred at 260 m μ . Although its concentration is low, and the absorption therefore weak, there is clear indication of hypochromicity in this band, which supports the view that the 4-thioUMP forms part of the double-helical structure. After oxidation the effect is lost, although a shifted long-wavelength absorption can still be seen.

That the 4-thiouracil can indeed pair with adenine in a helical structure has just been demonstrated by Scheit (Biochim. Biophys. Acta, 145, 535, 1967), who has prepared copolymers of UMP and 4-thioUMP, and complexed them with poly A. Hypochromism is observed both at 260 and 330 mµ—where the thionucleotide absorbs. Only three-stranded complexes appear to be formed at room temperature, but temperature-absorbance profiles show two phases, which by analogy with the intensively studied poly (A+2U)system suggests that in a certain temperature range the two-stranded form is stable. It is clear, however, that the A-thioU pairing is much weaker than A-U; this is consistent with the observations of Lipsett and Doctor on the apparent readiness with which basepairs involving 4-thioUMP are broken to allow the formation of internal disulphide bonds.

One would hesitate at this juncture to hazard any guesses at the possible purpose of thionucleotides in in tRNA. It is nevertheless perhaps interesting to store the information alongside the recently demonstrated effects of sulphydryl-blocking reagents on the function of *E. coli* ribosomes (see, for example, Traut and Haenni, *Europ. J. Biochem.*, 2, 64; 1967).

They Wobble

from our Cell Biology Correspondent

In the latest two papers from Khorana's laboratory, Söll, Cherayil and Bock, and Söll and RajBhandry (J. Mol. Biol., 29, 97 and 113; 1967), summarize their results on the coding specificities of yeast and E. coli tRNA. Their data are in striking agreement with Crick's (1966) Wobble hypothesis.

Because the genetic code is highly degenerate, Crick predicted that one species of $t{\rm RNA}$ can recognize more than one codon. An unambiguous demonstration of this requires homogeneous $t{\rm RNA}$ and a technique to study interactions. But now between codons and anti-codons $t{\rm RNA}$ species can be isolated in a sufficiently pure form to allow meaningful experiments, and Nirenberg and Leder (1964) have found that the interaction can be detected by binding $t{\rm RNA}$ to ribosomes programmed with tri-ribonucleotides (single codons). The synthesis, in Khorana's laboratory, of

ribopolynucleotides of known base sequence has provided another method, more reliable, for the determination of codon specificities, for it makes it possible to find what amino-acids are incorporated into a cell free system programmed with polymers of known sequence.

Söll et al. deduce three general principles of tRNA specificity from their binding experiments. First, if two codons specifying one amino-acid begin with different bases, they are recognized by two tRNAs. Second, one species of tRNA can only recognize three codons if these have the first two bases in common and U, C or A as the third base (for these pair with inosine in the anticodon); two codons are recognized by one tRNA only if the first two bases are the same and the the third either A or G or U or C, but not if one codon ends in a purine and the other a pyrmidine. Third, tRNAs specific for only one codon always recognize codons ending in G. These results agree with the Wobble hypothesis that there should be strict Watson-Crick pairing between the first two bases of the codon and anticodon, and that in the third there may be pairing between bases not included in the strict Watson-Crick prescription-G with U, for example. Wobble theory also predicts that anticodons which recognize three codons contain inosine. In support of this, Söll et al. find that of the tRNA species for thirteen amino-acids tested, three from yeast but only one from E. coli recognize three codons and Hall (1963) reported yeast tRNA is richer in inosine than tRNA from E. coli.

Formyl methionine tRNA which recognizes GUG and AUG codons at chain initiation is the sole exception to these rules. So either two species of Fmet tRNA exist, one for each codon, which have not yet been separated or, because Fmet tRNA binds to the peptidyl site in ribosomes, instead of the amino-acyl site different Wobble rules apply. (Wobble of the first base pair instead of the third, for example.)

In the second paper, Söll and RajBhandry report experiments with ribopolynucleotides which verify the coding specificities of seven species of tRNA determined by binding experiments and provide even more convincing evidence for multiple codon recognition and wobble. Yeast phenylalanine tRNA translated both UUU and UUC. Wobble theory predicts an anticodon GAA, not AAA, for this molecule. The primary sequence of yeast phenylalanine tRNA does not contain the sequence AAA but does contain the sequence 2'0-methyl GAA which must be the anticodon (RajBhandry et al., Proc. US Nat. Acad. Sci., 57, 751; 1967). As predicted by Wobble theory, G in the third anticodon position must pair with C or U in the third position in the codon because both UUU and UUC are translated.

Both binding and incorporation experiments also indicate the redundancy of several tRNA species; one codon is recognized by two different tRNAs. Such redundancy provides safeguards against mutation and offers a neat explanation of the origin of suppressor tRNA

Theoretical Astronomy at Cambridge

by F. L. WEST WATER

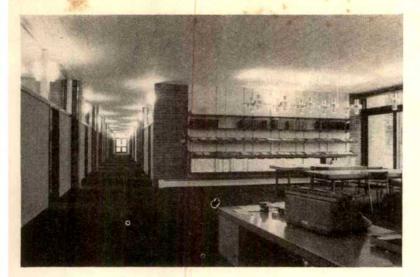

The Institute of Theoretical Astronomy at Cambridge will be formally opened next Tuesday by Sir Isaac Wolfson

THE institute under its director, Fred Hoyle, is equipped with its own computer and should not only provide a focus for theoretical astronomy in Great Britain but is certain to attract visits from other workers in the United States and elsewhere.

Although the need for such an institute was recognized as far back as 1959, and Government support would almost certainly have been made available, progress was seriously hampered because of disagreement over the location of the institute. Hoyle has always supported Cambridge, not because of his personal association with the university but more because he felt that the strong mathematics faculty with its great traditions would always attract as students the brightest young mathematicians in the country. Furthermore, the

amenities and reputation of Cambridge provide an inducement for visitors from abroad. There were others, however, who felt that one of the new universities should be chosen and there was also at this time a lack of enthusiasm for the idea in Cambridge itself.

In 1964, thanks to the interest taken by Lord Todd and the late Sir John Cockcroft, offers of financial help were promised by the Nuffield Foundation and the Wolfson Foundation. Further support from the Government was provided by the Science Research Council and agreement was reached that the institute should be at Cambridge on the understanding that the university also lent its support. In the event, the Wolfson Foundation has provided the buildings at a cost of about £180,000, and finance to run and equip the institute for five years has been provided by contributions of £250,000 from the Nuffield Foundation, £25,000 from the SRC and £125,000 from the University of Cambridge. The intention is that the bulk of the SRC contribution should be devoted to paying for the installation of the computer—an IBM

360/44. The remainder of the grant will suffice to pay for routine maintenance and single-shift operation for the period of five years.

The SRC has raised no objection in principle to the computer being used by other scientists in Cambridge, provided the needs of the institute are first fully met, but the additional costs involved must, of course, be provided by the users. One of the organizations to take up this offer is the Microbiological Unit of the Medical Research Council, which has been promised 1,000 hours a year for two years. Other users include the Cavendish Laboratory, the Chemical Laboratory and the

Department of Geophysics.

Discussions on the relationship of the institute with the university and the various faculties were protracted, but it was finally agreed that the institute should not be attached to any faculty and should come under the supervision of the general board of the university. For this reason, the institute staff is not permitted to give undergraduate lectures unless specially requested. spite of this restriction—or, as some may think, advantage—it is the wish of the university that other astronomers in Cambridge should be associated with the institute as closely as possible. General control of the institute is vested in a committee of management on which the Wolfson Foundation, the Nuffield Foundation, the Science Research Council and various university faculties are represented.

It will be for the institute to demonstrate its value during the five year period, after which new arrangements will have to be made. One must hope that it will be possible for the university, through the University Grants Com-

mittee, to continue the project.

The final administrative details were completed in the late summer of 1966 and the institute was established by statute on August 1. A site next to the existing observatories on the Madingley Road was obtained and work started in August 1966. The computer block was completed in February 1967 and the main institute buildings were ready for occupation in August 1967-surely a remarkable achievement. Present research staff numbers twelve, but this is likely to be increased to twenty within the next 2 years. All are post-doctoral appointments and are held for 3 years. A limited number of research students up to a maximum of sixteen can be accepted.

It is clear that a research institute in such a subject as theoretical astronomy cannot function properly without an interchange of ideas with workers in other countries and for this reason provision has been made to enable members of the staff to carry out visits to other centres. Finance is also available to invite and pay a number of visiting fellows from other countries, for periods varying from a few weeks to a year. The high degree of collaboration which already exists between Hoyle and the staff of the California Institute of Technology has been a considerable asset, and during the past summer, even before the institute was complete, five visiting fellows from California spent most of the summer in Cambridge.

With the completion of the buildings and the computer now working in two shifts, the activities of the institute can be expected to build up steadily during the current academic year. A series of graduate lectures has been arranged for the present session and these are being well supported. Contact with the undergraduate body is being maintained by a series of lectures given by Hoyle who, of course, retains his position as Plumian professor of astronomy and experimental philosophy in the university. It is hoped that it will be possible to arrange one or possibly two Foundation Lectures each year to be given by distinguished workers in astronomy or allied fields. Consideration is also being given to holding symposia on special subjects to which experts will be invited at the institute's expense. Plans are also being prepared to enable the institute to play its part when the International Astronomical Union visits England in 1970.

Technology in Scotland

by NIGEL HAWKES

Is there a technological revival in Scotland? And will it bring prosperity?

For almost forty years, Scotland languished as a technological backwater. Ironically, it was probably the industrial success of the nineteenth century which set the scene for the disasters of the twentieth. Until the end of the First World War, Scotland was unsurpassed as a centre of engineering excellence, and for a time imperial expansion was a guarantee of new markets. After the war, things began to go wrong; the old industries-coal, engineering and shipbuilding-found that their products were harder to sell. The new industries were all in England. As a result, the depression hit Scotland particularly hard. During the thirties, unemployment never fell below 11 per cent, and at its worst reached an unprecedented 34 per cent. Graduates from Scottish universities either went on the dole or moved to England for work. The situation graphically demonstrates what can happen when industry becomes detached from technological progress. Since the Second World War, the situation has begun to right itself; or, to be more accurate, the Scots themselves have set about righting it. Much of the credit for this must go to the Scottish Council, the first regional development council, which has originated many of the policies now followed by other councils in other development areas. The council has been aided by the policies of central government, which has encouraged the settlement of new industries in development areas by investment grants, and sometimes by the less subtle expedient of refusing to let companies expand where they were. Mistakes have undoubtedly been made, but the result of these policies has been a good one, and the scientific climate in Scotland is now in many ways more encouraging than that in England.

The greatest success story of all has been the establishment in Scotland of a substantial electronics industry. The major element in this is the Ferranti Company, which has invested £3 million in developments in Scotland, and employs 5,000 people there. Ferranti first went to Scotland in 1943 and established a factory for the manufacture of gunsights. Since the war, expansion of Ferranti activities has been continuous, and the Scottish group includes several research laboratories, an important element in industrial development. The progress of Ferranti has encouraged other electronic companies to come to Scotland, including two companies from the United States. An even more encouraging sign is the development of small companies spawned by the presence of the others, and a conscious effort is being made to encourage an atmosphere like that around the technological centres in the United States. At the department of engineering at Edinburgh University, a new postgraduate retraining course in micro-electronics begins this week. Intended for designers in industry whose training finished before the new micro-electronic techniques were invented. the course is staffed from industry, and consists of six three-week courses separated from each other by five week breaks in which the designers being retrained will return to their firms. Thus, although the course lasts 11 months, engineers need be away from their firms for only 18 weeks. Although the course deserves to be oversubscribed, so far industry is treating it gingerly. The university, at least, cannot be accused of dragging its heels—the plan was put before the university court in March this year, and by the beginning of November the buildings were up, in part at least, and ready for their

Another industry of some growth potential is the supply of desalination equipment. Weir Westgarth, of Glasgow, has so far supplied half the world's capacity in large scale desalination equipment. Recently the company opened a new research and development centre at Troon, where desalination techniques, particularly flash distillation, will be studied. Flash distillation is a simple process; brine, pre-heated by low grade steam, passes through a series of chambers at decreasing pressure, so that it boils in each one. In each chamber the pure water boiling off is collected on condenser tubes. Essentially the problem is to improve the heat transfer and the efficiency of the process, and much of the work at Troon will attempt to achieve this. Other methods of desalination may also be tried, although there is only one—reverse osmosis-which seems to offer a serious rival to flash distillation. One of the company's minor difficulties is that of enforcing its patents in the United States—a problem shared, incidentally, by a number of British and Continental companies. Patent litigation takes so long to come to court in the US, and the results are so unpredictable, that British companies are often happy if they can negotiate offset agreements allowing them to use US patents in exchange for their own. Recently Weir Westgarth has become involved with the Atomic Energy Authority in some joint studies of combinations of desalination plant

with nuclear power stations. The danger of this approach is that prospective customers will come to feel that they can only buy a desalination plant if they are also prepared to fork out for an advanced gas cooled reactor at the same time; a complete misconception, as Weir Westgarth is at pains to point out.

Not all Scotland's industry looks as well placed as this. Privately, staff from the Scottish Council will agree that it was a mistake to force British motor companies to expand in Scotland; the motor component industry, which it was hoped would follow BMC and Rootes to Scotland, has not appeared. Shipbuilding is another headache, made worse by the reluctance of the large shipyards to take on anything but full-blooded ships. If more of the yards were ready to build large engineering constructions, like the oil rigs which some are already building, they would find it easier to get work. John Browns, which is building the Queen Elizabeth II, is said to be particularly stiff-necked. And coal mining, of course, is bound to decline even further as the prospects of getting another coal fired generating station in Scotland fade. But the Scottish Council is making sure that Scotland's claim for one of the new aluminium smelters does not go unheard; the preferred site is at Invergordon.

All this development needs better communications between Scotland and the rest of the world. One of the crucial factors in the developments of the last ten years has been the arrival of the airlines, or more precisely the airline, since British European Airways has a monopoly on many of the routes. In Scotland as elsewhere it is easy to find people who believe that the BEA monopoly is wrong, and that competition would help both to bring down prices and to make seats on the aircraft easier to come by. At the moment it is often necessary to book several weeks in advance for flights to London, which business men find very inconvenient. For all this, there is no doubt that BEA has transformed life in the Highlands and the Islands, which are now within ready reach of Glasgow and Edinburgh.

In science, Scotland has potentially the greatest growth point in the UK. Aberdeen could well become the British centre for oceanography and marine science. Already it has the Torry Research Station, the Marine Biological Laboratory, and a Unilever laboratory which is investigating methods of farming fish. On the agricultural side, Aberdeen boasts the Rowett Research Institute and the Macauley Soil Institute. This is a concentration of excellence which it would be hard to equal anywhere else, and the staff of the laboratories are full of ideas for improving Scotland's fisheries and farms. One of these is the hope of developing new fisheries on the west coast of Scotland, hitherto unfished because there is no port of sufficient size. There are apparently substantial amounts of valuable shellfish simply waiting for exploitation, and the first step would be to establish a factory for deepfreezing the fish before transport to the south. Unilever is experimenting with the cultivation of lobsters and prawns, because expensive fish offer the best chance of commercial success in fish farming.

All this makes a pleasing contrast with the condition of Scotland between the Wars. But in future the job is likely to be even harder—for one thing, the rest of the United Kingdom is going to have to woo advanced industry in the way demonstrated by Scotland, which is bound to make the Scottish problem worse. in Scotland is that the process has now gone far enough to be a self-generating one, but this may be over-optimistic. Undeniably, though, some of the Scottish Council's statistics are impressive. In 1959, only one in sixteen of the workers in Britain in high technology industries worked in Scotland; now the figure is one in eight. Scotland's exports are up by 50 per cent in the five years from 1961. Even the squeeze seems to have been less severe over the border—unemployment is up by 50 per cent, but in England the increase has been 84 per cent.

Underwater Vision of the Sea Otter

by R. L. GENTRY R. S. PETERSON Division of Natural Sciences, University of California, Santa Cruz

A sea otter, Enhydra lutris, was trained to select the larger of two disks simultaneously presented under water, and its ability to discriminate between disks of nearly the same size was tested. results provide an index of visual acuity, and suggest that Enhydra has slightly poorer underwater vision than Zalophus or Phoca.

As the ancestors of modern aquatic mammals moved from land to water, adaptation of sensory organs may have been critical. Variations in the underwater effectiveness of visual systems may therefore accurately suggest the degree of adaptedness of different species to the aquatic

Schusterman et al.1 measured the ability of California sea lions (Zalophus californianus) to discriminate visually under water between disks of different sizes, and Feinstein and Rice2 used the same technique to test harbour seals (Phoca vitulina). Both species could make very fine size discriminations under water, and their underwater visual acuity must be excellent. This finding is consistent with

their high degree of aquatic adaptation.

In lacking pectoral limbs modified for swimming, and in lacking a streamlined body form, Enhydra seems less adapted to the open sea than do pinnipeds (for discussion compare ref. 3). Kenyon showed that sea otters are usually found in the littoral zone, although they make short trips on to land and to the open sea4. Otters and pinnipeds are morphologically and behaviourally dissimilar, so that sensory differences may be expected. We have tried to reveal existing differences in underwater visual discrimination between Enhydra, Zalophus and Phoca.

We tested the only sea otter known to us to be in captivity, a male at Point Defiance Aquarium, Tacoma, Washington. Captured in Alaska 14 months before testing, the animal was between 4 and 5 yr old and weighed 75 lb. Its daily food ration, 15 lb. of fish and squid, was maintained during testing, and was dispensed in three portions each day during the experimental procedures. Training and testing from March 13-26, 1967, were carried out in the $2 \times 4 \times 8$ ft. (0.6×1.8) × 2.6 m) wooden tank in which the animal had been held since capture.

We used a test apparatus (Fig. 1) similar to that used for testing the underwater vision of Zalophus and Phoca^{1,2}. This device presented two targets 20 in. (50 cm) apart separated by an 18 in. (45 cm) divider. For test targets we used a size graded series of nine white painted metal disks of the following sizes: 67, 86, 96, 101, 108, 114, 122, 137 and 174 cm2. After 4 h of training, the animal would dive, swim the length of the tank under water, and strike a training target (the 108 cm2 or standard target of the series) to receive a reward of a 10 g piece

To determine whether the subject had a pre-existing preference when faced with two targets of different sizes, we simultaneously presented the largest and smallest targets in the series for thirty-five trials, rewarding responses to either target. The animal selected the larger target in twenty-one of the trials, suggesting a slight preference. In all subsequent experimentation we rewarded responses to the larger target only. To establish this response firmly, we then ran 360 additional presentations. At the end of these training trials, performance had reached virtually 100 per cent correct and testing was initiated.

The method of constant stimuli (ref. 5, page 118) was used in these tests. Each of the eight targets in the series was paired with the standard (108 cm2) target for ten trials in each test session. The position of the larger target was alternated randomly using a standard Gellerman series and the sequence of the target pairs was also randomized from one session to the next. The subject received usually three sessions of eighty trials each day during three days of testing.

We estimated the discrimination ability of the otter by the percentage of correct responses it made in ninety trials with each of eight pairs of targets (Fig. 2 and

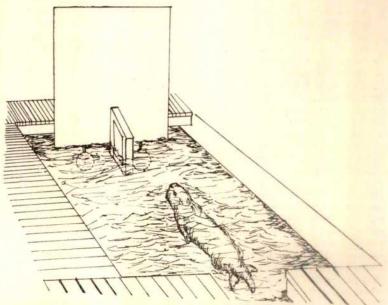

Fig. 1. Sea otter making an underwater approach to targets suspended from the test apparatus.

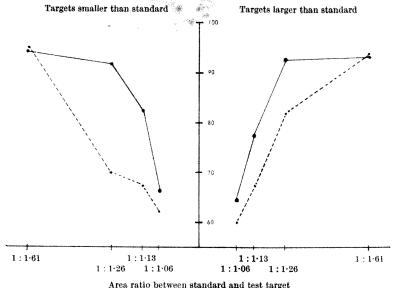

Fig. 2. Comparative performance of Zalophus (——) and Enhydra (---) on a size discrimination task.

Table 1). When two very different targets were presented (area ratio of 1:1.61), the animal selected the larger target about 95 per cent of the time. When the two targets were nearly identical (area ratio of 1:1.06), the percentage of correct responses was approximately 60 per cent.

Table 1. SIZE DISCRIMINATION TESTS ON SEA OTTER

Ratios between areas of targets	No. of sessions of ten trials	Mean performance level	Standard deviation
(Targets smaller tha	n standard)		
1:1.61	9	9.5	0.498
1:1.26	9	7:0	1.764
1:1.13	9	6.7	1.397
1:1.06	9	6-2	1.812
(Targets larger tha	n standard)		
1:1.06	8	6-0	1.323
1:1.13	9	6.7	1.315
1:1.26	9	8.4	0.956
1:1-61	9	9.4	1.066

The table shows relative performance levels at different sessions.

Data given by Schusterman et al.1 for two sea lions show mean levels of performance similar to those of the sea otter at very high and very low area ratios. The performance levels of the two species diverge at intermediate ratios, however. The amount of divergence can be measured by finding the 75 per cent performance level, a commonly used approximation of the threshold at which discrimination ability becomes useful to an animal. At that level, Zalophus seemed able to make finer discriminations in area than Enhydra.

The data also suggest that the otter performed better when comparing targets with a large absolute size than when comparing those of smaller size, despite the fact that area ratios were exactly the same (see particularly the two points for area ratio 1:1.26, Fig. 2). It is possible that absolute size, as well as area ratio, may be involved in the otter's ability to make discriminations in the size range tested, although data on Zalophus and Phoca indicate no such dependence.

The optics of the eyes of amphibious mammals are poorly understood. The morphology of the eye of Zalophus and Phoca is quite different from that of otters. The pinniped eye functions normally (is emmetropic) under water and possesses some special adaptations for aerial vision. Its lens, adapted for use under water, is

not used in air, but instead the iris is closed to a tiny aperture which serves as a "pin hole lens". Conversely, the eye of the otter (Lutra) is emmetropic in air and has some special adaptations for vision under water. While submerged, well developed ciliary and sphineter muscles in the otter's eye strongly distort the anterior part of the air adapted lens, giving it a focal length similar to that of a spherical lens. It would not be surprising, then, to find that Zalophus and Phoca can see somewhat better under water than can Enhydra, as our data suggest, because the lens of the pinniped eye appears highly specialized to function under water, while that of the otter is amphibiously adapted.

It is possible that retention of sharp air vision has been ecologically more important to Enhydra than the evolution of adaptations for acute underwater vision. For example, terrestrial predators might have been more significant in the ecology of this littoral zone inhabitant than for a more pelagic species. Field studies have shown that Zalophus is slow to respond to threatening visual stimuli, such as an approaching man, in air6. R. J. Schusterman (personal communication), however, has

tested the ability of this species to make size discriminations in air, and found it very similar to the underwater performance. We could not test aerial vision on the Tacoma sea otter, unfortunately; the animal did not respond when the targets were presented above the surface of the water.

If strong accommodation accounts for the otter's underwater visual abilities, we wondered whether a typical land mammal, such as man, could accommodate as well over short distances while submerged. We repeated the test procedures using two students as test subjects. When the pairs of disks of most nearly the same size (area ratio of 1:1.06) were presented, the humans achieved performance levels of approximately 80 per cent in forty trials at a distance of 3 ft. This was a decrease of 20 per cent from their performance in air. These results cannot be compared directly with results of tests on marine mammals because of testing differences such as the longer response latency of humans. trials show, however, that land mammals can probably accommodate as well at short underwater distances as sea otters can. The tests also show that comparison of disks for approximating visual acuity can reveal acuity differences of the magnitude of those experienced by a human entering water from air. This method is therefore useful for finding visual differences among some aquatic But when the differences in acuity become relatively small, as between Zalophus, Phoca and Enhydra, more sensitive measurements (such as Landolt's broken ring test) seem warranted.

We thank the US Fish and Wildlife Service and the Tacoma Zoological Society for permission to study their captive otter and for their assistance. We thank Čecil A. Brosseau, Dr M. L. Johnson, Karl W. Kenyon and Dr Victor B. Scheffer for their help. Ronald J. Schusterman lent the targets, and Victor Downing and Thomas Snyder were the human test subjects.

Geomagnetic Reversals and Pleistocene Chronology

by
B. GLASS
D. B. ERICSON
B. C. HEEZEN
N. D. OPDYKE
J. A. GLASS

Lamont Geological Observatory, Columbia University, New York The palaeontology and palaeomagnetic stratigraphy of several Atlantic and Pacific cores has been determined to establish the age relationship of various palaeontological boundaries which have been used to define a Pliocene—Pleistocene boundary in deep sea sediments.

STUDENTS of the Quaternary have turned to the slowly accumulating pelagic sediments of the deep sea in their quest for a complete and concise record of this latest chapter of Earth history, but, because foraminiferal oozes are deposited at a rate of about 2.5 cm/1,000 yr (according to radiocarbon dating), the cores which are 5–15 m long usually fail to penetrate completely the

pelagic Quaternary sequence. Because of post-depositional disturbances such as slumping, however, truncated and discontinuous early Quaternary and Tertiary sequences have been recovered in long cores.

Ericson, Ewing and Wollin^{1,2} constructed what they believed to be a complete Pleistocene stratigraphic section by piecing together and correlating overlapping sequences recorded in twenty-six cores. They based their reconstruction on climatic curves (determined from the relative number of Planktonic foraminifera from cold and warm water, Fig. 1) and changes in the direction of coiling of Globorotalia truncatulinoides (Fig. 2). In addition, they established the following faunal criteria for defining a Pliocene-Pleistocene boundary in deep sea sediments: (1) extinction of Discoasteridae, the organisms responsible for secreting the minute star-shaped objects called discoasters; (2) extinction of Globigerinoides sacculifera fistulosa above the boundary; (3) appearance of Globorotalia truncatulinoides in abundance above the boundary; (4) change in the direction of coiling of the members of the Globorotalia menardii complex from 95 per cent coiling to the right below to 95 per cent coiling to the left above the boundary; and (5) marked increase in size and wall thickness of the tests of members of the G. menardii complex above the boundary.

The thickness of the zone, within which these changes occur, differs somewhat in the various cores. In order to have a common level of reference in all the cores containing the boundary, Ericson et al. defined their boundary by the change in coiling direction of the G. menardii complex. By extrapolating beyond 175,000 yr they established a time scale for their Pleistocene stratigraphic section and arrived at an

age of 1.5×10^6 yr for their Pliocene-Pleistocene boundary (Fig. 1). They had, however, no method of determining the relationship of this boundary to faunal boundaries observed in Pacific and Antarctic sediments and they could not correlate their boundary with the officially adopted Pliocene-Pleistocene boundary³ at the base of the Calabrian in Italy.

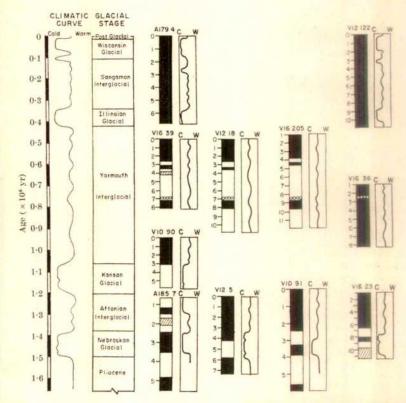

Fig. 1. The Pleistocene stratigraphic section of Ericson et al. showing ten of the twenty-six cores originally used by them. The generalized climatic curve on the left is based on variations in abundance of various temperature-sensitive planktonic foraminifera. The correlation between this curve and continental glaciation is also shown. The time scale, based on sedimentation rates determined from radiocarbon and protactinium-lonlum measurements and extrapolated down through their Pleistocene section, is shown to the extreme left. The correlation between the cores and the climatic curve is indicated by the position of the cores in the figure. The extinction of Globorotalia sp. 1, according to Ericson et al., is indicated by a horizontal line of open circles across cores V16-39, V12-18. V16-205 and V16-36. The palaeomagnetic stratigraphy of each core, according to this paper, is designated by black (normal) and white (reversed).

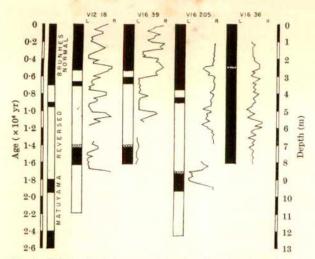

Fig. 2. Relationship between variations in coiling direction of Globorotalia truncatulinoides² and magnetic stratigraphy. The relationship between changes in coiling direction of G. truncatulinoides and the magnetic stratigraphy shows almost perfect correlation between cores V12-18 and V16-39. Correlation between these two cores and V16-205 is fairly good. There is, however, no correlation between these three cores and V16-36, indicating that it is misplaced in the Pleistocene stratigraphic section of Ericson et al. In addition, the horizontal line of open circles indicates the last occurrence of Globorotalia sp. 1. In V12-18, V16-39 and V16-205, this species becomes extinct immediately above the Olduvai event. In core V16-36, however, it disappears in the middle of a long normal interval, again indicating that this core is misplaced in the stratigraphic section of Ericson et al.

Palaeomagnetic studies of volcanic rocks on land have established and dated by potassium—argon a series of reversals of polarity of the Earth's magnetic field^{4,5}. It is known that the Earth's field has had its present or normal polarity for the last 700,000 yr and that for approximately 1·8×10⁶ yr before that it had an opposite or reversed polarity, except for two periods of short duration (<200,000 yr). The reversed and normal intervals of long duration are called epochs and the shorter intervals are called magnetic events (Fig. 3). It has recently been shown that the remanent magnetism of deep sea sediments is sufficiently strong and stable that these polarity reversals can be used to date and correlate

geological events recorded in these sediments throughout the world during the past four million years^{6,7}.

In order to date the Pliocene-Pleistocene boundary of Ericson et al. and to determine the relationship between their boundary and presumedly equivalent faunal boundaries in the Pacific and Antarctic Oceans, the palaeomagnetic stratigraphy of several cores from the stratigraphic section of Ericson et al. and several Pacific cores was determined.

In order to establish the magnetic stratigraphy, each core was sampled every 10–50 cm. The intensity, relative declination and inclination of each sample were measured on a 5 c/s spinner magnetometer⁸ after the sample had been partially demagnetized in an alternating field of 50–100 oersted in order to remove unstable components. Reversals are indicated by simultaneous changes in the sign of the inclination and 180° shifts in declination (Fig. 4).

We were able to determine the palaeomagnetic stratigraphy of thirteen of the thirty-four cores used by Ericson et al. to establish their Pleistocene stratigraphic section (Table 1, Figs. 1 and 3). The upper part of the sequence based on dozens of nearly identical climatic curves had been deposited entirely during the present period of normal polarity. The magnetic stratigraphies showed that several of the cores assigned to the earlier Pleistocene by Ericson et al. had been miscorrelated. Three of these, however (V12–18, V16–34 and V16–205), which they regarded as being of middle Pleistocene age, actually contain a reasonably clear and complete record of magnetic reversals and faunal changes during the past 2–2·5×10° yr.

Although most of the cores which contain their Pliocene-Pleistocene boundary show evidence of depositional hiatuses at or near the boundary, it is evident that sediment accumulation across the boundary was continuous in two—that is, cores A185-7 and V10-91—of the five in which meaningful magnetic measurements could be made.

By correlating the palaeontology with the magnetic stratigraphy (Fig. 5) we were able to date several palaeontological boundaries used by various authors to define a Pliocene-Pleistocene boundary in Atlantic and Pacific sediments. Discoasters and planktonic foraminifera,

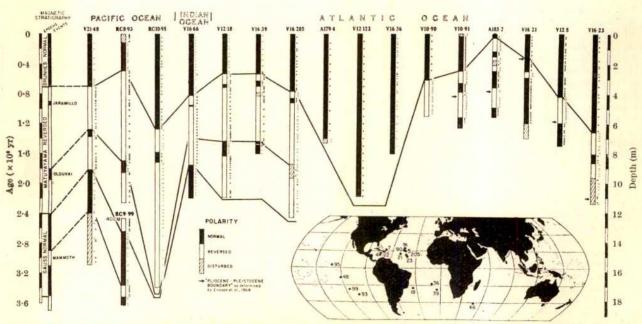

Fig. 3. Correlation of deep sea magnetic stratigraphy with magnetic stratigraphy dated on land by potassium-argon. Positive polarity is normal in the northern hemisphere and reversed in the southern hemisphere. Disturbed sections, resulting from coring, are often present at the top or bottom of a core.

* Based on carbon-14 measurements from Ericson et al.*

† Based on the lengths of what we assume to be the Jaramillo and Olduvai
events.

Globigerinoides sacculifera, thought to define the Pliocene-Pleistocene boundary in Atlantic and Pacific sediments^{1,8}, became extinct at the Olduvai event (Fig. 5) about 1·8 × 10⁶ yr ago. (The occurrence of rare or scattered discoasters and G.s. fistulosa in younger sediments is probably the result of the reworking of old sediments into younger sediments by bottom currents and benthonic organisms.) In core V21-48 G.s. fistulosa first appears in sediments of the Gauss normal magnetic epoch and thus seems to have a range of about 1 × 10⁶ yr or less.

Globorotalia truncatulinoides first appears just below the Olduvai event both in Pacific and Atlantic cores. Banner and Blow¹⁰, working in the Calabrian type section in Italy, have shown that G. truncatulinoides evolved from G. tosaensis at the Pliocene-Pleistocene boundary. Thus for the first time deep sea sediments can be correlated with the type Pliocene-Pleistocene section in Italy. Because G. truncatulinoides first appears immediately below the Olduvai event, the Pliocene-Pleistocene boundary must have an age of about 2×10^6 yr.

Bed I in the Olduvai Gorge in Tanzania, which has been dated at 1.8×10^6 yr (ref. 11), contains upper Villafranchian fauna, which supports an age of about 2×10^6 yr for the Pliocene–Pleistocene boundary, because the Villafranchian is accepted as the continental equivalent of the Calabrian stage³. In addition, Selli¹² by extrapolation of sedimentation rates, has arrived at a date of 1.8×10^6 yr for the Pliocene–Pleistocene boundary in the Calabrian section in Italy.

The Globorotalia menardii complex changes coiling direction about midway between the Gauss-Matuyama boundary and the Olduvai event in Atlantic sediments, but in Pacific sediments (core RC9-99) this change occurs near the Mammoth event (Fig. 5). Thus the boundary of Ericson et al. has an age of about $2 \cdot 1 \times 10^6$ yr in Atlantic sediments.

Sphaeroidinella seminulina and S. subdehiscens last appear in abundance at the top of the Mammoth event in Pacific cores (V21-48 and RC9-99). Sphaeroidinella dehiscens makes its first appearance at this point and is abundant in most cores up to the Matuyama-Brunhes boundary where it becomes rare. This decrease in abundance seems to remain through the Brunhes normal epoch.

The extinction of the radiolarian Pterocanium prismatium, used to define a Pliocene-Pleistocene boundary

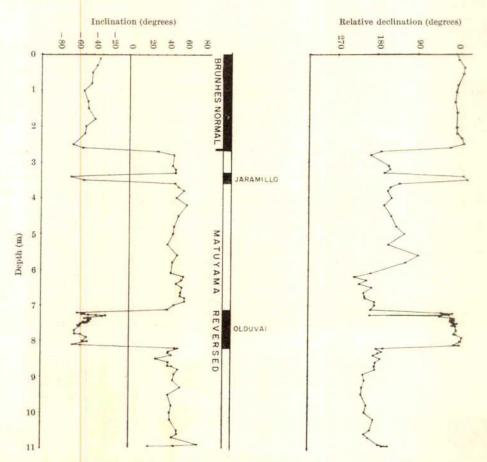

Fig. 4. Correlation between inclination, relative declination and magnetic stratigraphy in core V12-18. Magnetic reversals are indicated by change in sign of the inclination and 180° shifts in declination. Because the core is from the southern hemisphere, samples with a negative inclination are normal and samples with a positive inclination are reversed.

in Pacific sediments13, has been correlated with the last magnetic reversal14. The extinction of this radiolarian. however, has also been correlated with discoaster extinction13 and we have shown that discoasters became extinct during the Olduvai event. Thus it would seem that P. prismatium must have become extinct near the Olduvai event rather than at the Matuyama-Brunhes reversal. This conclusion is supported by core RC10-95 in which P. prismatium becomes extinct approximately simultaneously with discoasters and both extinctions seem to be close to the Olduvai event. (Although the magnetic data are not clear in the bottom of this core, extrapolation of sedimentation rate from the Matuyama-Brunhes reversal indicates that the bottom of the core is near the Olduvai event. This conclusion is supported by the presence of discoasters in abundance up to about

Core V16-205 contains all the faunal changes cited by Ericson et al. as occurring at or near their boundary. According to the magnetic reversals the evolutionary changes in the G. menardii complex took place about $2\cdot 1 \times 10^6$ yr ago. The first appearance of G. truncatulinoides in this core occurred 2.0 × 106 yr ago, and was followed by the extinction of G.s. fistulosa about 1.8×10^6 yr ago. The Discoasteridae seem to have died out between 2.0 and 1.8×10^6 yr ago.

Several of the palaeontological changes defining the boundary of Ericson et al. occur in core V12-18. These changes have the same relationship to the magnetic stratigraphy indicated in core V16-205. In addition, McIntyre¹⁵ finds a continuous evolutionary change in the coccolith assemblage between 700 and 850 cm in this core which he has also observed across the boundary of Ericson et al.1 in other cores.

Now that it is known where the Pliocene-Pleistocene boundary of Ericson et al. occurs with respect to the magnetic stratigraphy, several cores in which they identified their boundary can be examined.

In core V16-23 S. dehiscens is rare if not absent in the normal zone, in the upper half of the core, and abundant in the reversed zone below (Fig. 3), thus indicating that the normal zone of this core is the Brunhes normal epoch. The short normal zone at about 8 m is probably the Jaramillo event. The occurrence of the boundary of Ericson et al. at the bottom of this core must therefore be the result of a hiatus with about 650,000 yr missing.

Sphaeroidinella dehiscens is also rare in the normal zone at the top of core V10-91 and more abundant in the reversed zone below, indicating that the normal zone is the Brunhes normal. The normal zone at about 3 m might be either the Jaramillo or the Olduvai event, but the presence of discoasters in abundance part of the way through this zone indicates that it is probably the top of the Gauss normal. There is therefore a hiatus present in this core also, but it is probably above the Olduvai event. There is no evidence of discontinuity across the Pliocene-Pleistocene boundary of Ericson et al.

The complex magnetic stratigraphy of core A185-7 indicates several hiatuses and the palaeontology indicates some reworking. The short normal zone at the top of the core is probably Brunhes normal because S. dehiscens is rare if not absent in it and abundant in the reversed zone below. Discoasters extend up to just below the normal zone between 245 and 360 cm indicating that this normal zone is the Olduvai event. G. truncatulinoides, however, which is usually abundant down to the Olduvai event, only occurs in abundance down to about 150 cm, and is rarely observed down to where discoasters become extinct. S. semulina and S. subdehiscens are present up to a depth of 470 cm and S. dehiscens is present from there to the top of the core. This boundary occurs in the Gauss normal epoch in cores V21-48 and RC9-99 from the Pacific. There must therefore be a large hiatus in the bottom of this core. There must also be a hiatus between the Olduvai and Jaramillo events, and the abbreviated Brunhes normal section indicates a hiatus in the top of the core. The position of the boundary of Ericson et al. within the reversed zone and just below the Olduvai event, however, together with a layer by layer correlation of faunal changes in the boundary zone with the same faunal changes in core V10-91, indicates that the core is continuous across the boundary.

Core V16-21 is completely normal except for a short reversed zone between 250 and 285 cm. The decrease in abundance of S. dehiscens at 100 cm indicates that the top part of the core, at least above 100 cm, is the Brunhes normal. Because discoasters and G.s. fistulosa become extinct at about 150 cm and G. truncatulinoides first appears at about 150 cm, the boundary of Ericson et al. must represent a hiatus between Brunhes normal and Gauss normal sediments with the entire Matuyama section missing. The transition from S. subdehiscens to S. dehiscens at about 500 cm again indicates that the bottom part of the core is within Gauss normal sediments.

The decrease in abundance of S. dehiscens above 420 em in core V12-5 indicates that the normal zone at the top of the core is the Brunhes normal. The boundary of Ericson et al. occurs at a reversal which probably represents a hiatus with an incomplete Matuyama reversed

section lying on the top of the Gauss normal.

Three cores (V16-205, A185-7 and V10-91) contain a continuous record of faunal changes defining the Pliocene-Pleistocene boundary of Ericson et al. In cores A185-7 and V10-91, the time interval represented by this sequence is of the order of 0.2×10^6 yr. In core V16-205, however, it seems to be 0.3×10^6 yr, that is from 2.1 to 1.8×10^6 yr ago. The time interval, therefore, represented by the faunal changes defining the Pliocene-Pleistocene boundary of Ericson et al., is probably somewhere between 0.25 and 0.30×10^6 yr.

Hays¹⁶ defined a boundary, $\varphi - X$, in Antarctic cores based on the extinction of two radiolaria (Clathrocyclas bicornis and Eucrytidium calvertense) which he tentatively correlated with the boundary of Ericson et al. Opdyke et al.6 determined the palaeomagnetic stratigraphy of several Antarctic cores containing Hays' boundary and found that it occurs just below the Olduvai event about 2×10^6 yr ago. Core V16-66 from the Indian Ocean contains both the Pliocene-Pleistocene boundary of Ericson et al. and the $\varphi - X$ boundary of Hays. Because this core is from a high latitude, only two of the criteria for defining the boundary of Ericson et al. are present (extinction of discoasters and appearance of G. truncatulinoides). Both of these changes occur at approximately the same level as the extinction of C. bicornis and E. calvertense (Fig. 5) which defines the boundary of Hays.

Arrhenius¹⁷ defined a "Pliocene-Pleistocene boundary" in Pacific sediments on the basis of carbonate content. He placed his boundary at a level above which there was a marked increase in carbonate, on the supposition that abundant biogenous carbonate represented times of rapid oceanic circulation resulting from climatic deterioration. Riedel et al.13 found that discoasters and the radiolaria, Pterocanium prismatium and Eucrytidium elongatum peregrinum, became extinct in Pacific sediments approximately at the boundary of Arrhenius. We have shown that in the Pacific discoasters and P. prismatium became extinct at the Olduvai event. Thus the $\varphi - X$ boundary of Hays in Antarctic sediments and the Pliocene-Pleistocene boundary of Arrhenius based on carbonate content in Pacific sediments are approximately equivalent to the Pliocene-Pleistocene boundary of Ericson et al. in Atlantic cores.

The dates for the generalized climatic curve of Ericson et al. (Fig. 1) for the past 0.5×10^6 yr are assumed to be correct because the same sequence is found in several cores that have been dated by the radiocarbon², protactinium-ionium¹⁸, protactinium¹⁹ and thorium-230 (ref. 20) methods. This climatic curve is based on the variations in relative numbers of species of planktonic foraminifera the geographical ranges of which are known to be limited by

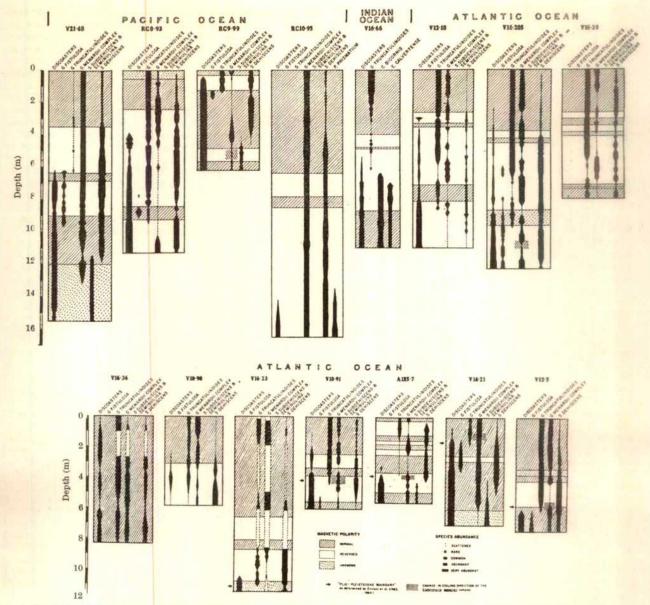

Fig. 5. Correlation between palaeontological changes and magnetic stratigraphy in ten Atlantic, one Indian Ocean and four Pacific cores. Where the biogenous component is not abundant the species abundance is shown by dashed lines.

temperature. Most of the cores in the remainder of their Pleistocene section are misplaced, however, and therefore their climatic curve below 0.5×10^6 yr is probably incorrect. We have shown, however, that three of the cores (V12–18, V16–39 and V16–205) from their Pleistocene stratigraphic section have an almost complete record of sedimentation for the past 2–2.4 × 10 6 yr. By correlating their climatic curves for these cores with the magnetic stratigraphy, a generalized climatic curve for the past 2.4 × 10 6 yr was obtained (Fig. 6). The climatic zones are designated by letters according to the system begun by Ericson et al. 21 .

Recorrelating the cores in accordance with the sequence of magnetic reversals increases the durations of the three earliest climatic events, Q, R and S. The S zone, considered by Ericson et al. to be equivalent to the Kansan Ice Age, now seems to include nearly as much time as the T zone, which Ericson et al. equated with the Yarmouth Interglacial.

Conolly and Ewing²² defined an ice-rafted boundary in Antarctic sediments which they believe indicates the initiation of glaciation in the southern hemisphere. The date of this boundary is 2.5×10^8 yr according to Opdyke et al.⁶ In addition the generalized climatic curve obtained from cores V12–18, V16–39 and V16–205 shows a cold zone extending back to 2.4×10^8 yr (Fig. 6). Thus, it seems that climatic deterioration began at least 500,000 years before the beginning of the Pleistocene.

Uffen²³ suggested that during reversals of the geomagnetic field the Earth's surface was subjected to an increase in cosmic-ray bombardment which caused a higher mutation rate which in turn affected evolution. The paper by Opdyke et al.⁶ showed that there was a striking correlation between radiolarian boundaries in Antarctic cores and geomagnetic reversals, thus giving some support to Uffen's hypothesis. It is obvious (Figs. 5 and 6) that several foraminiferal boundaries are also correlated with reversal boundaries, as well as the extinction of discoasters and Pterocanium prismatium, thus giving further support to Uffen's hypothesis.

In conclusion, we have shown that discoasters, G.s. fistulosa, Globorotalia sp. 1, and Pterocanium prismatium all became extinct near the top of the Olduvai event (1.8 × 106 yr ago). Sphaeroidinella dehiscens evolved from

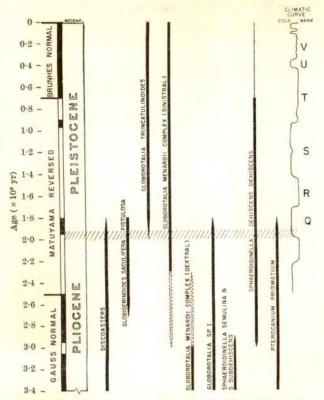

Fig. 6. Correlation of species range, climatic fluctuations and the Pliocene-Pleistocene boundary with magnetic reversals. The Pliocene-Pleistocene boundary based on the first appearance of G. truncatulinoides occurs at the base of the Olduvai event about 2-0×10° yr ago. Discoasters. G.s. fistulosa. Globorotalia sp. 1 and Pterocanium prismatium became extinct near the top of the Olduvai event (about 1-80×10° yr ago). Sphaeroidinella dehiscens evolved from S. subdehiscens at the Manmoth event (3×10° yr ago) and decreased in abundance at the Matuyama-Brunhes boundary. The generalized climatic curve is based on the interpretation of Ericson et al. and has been modified to accord with the sequence of geomagnetic reversals.

S. subdehiscens at the Mammoth event (about 3 × 10° yr ago) and decreased in abundance near the Matuyama-Brunhes boundary (Fig. 6).

The Pliocene-Pleistocene boundary of Ericson et al.1,2 defined by the change in coiling direction of the Globoro-

talia menardii complex occurred about 2·1×106 yr ago in the Atlantic Ocean, instead of 1.5 x 106 yr ago as suggested by Ericson et al., and it was followed by several other faunal changes which define a zone representing a time interval of about 0.25-0.3 × 106 yr.

The Pliocene-Pleistocene boundary, based on the first evolutionary appearance of Globorotalia truncatulinoides, occurs at the base of the Olduvai event about 2.0 × 106 yr ago (Fig. 6). A cold zone, however, in Atlantic cores extends back to 2.4 × 106 yr (Fig. 6) and ice-rafting recorded in Antarctic cores began at least 2.5 × 106 yr ago. Climatic deterioration therefore preceded the Pleistocene epoch by at least 500,000 yr.

We thank Eric Schneider who initiated this research and A. McIntyre, J. D. Hays and A. Kaneps for assistance with the palaeontology and helpful discussions. We also thank T. Saito and W. Broecker for help with the manuscript, and Goesta Wollin for his assistance. The research was supported by the US National Science Foundation.

Plutonium-244 in the Early Solar System and Concordant Plutonium/Xenon and Iodine/Xenon Decay Intervals of Achondrites

D. D. SABU P. K. KURODA Department of Chemistry, University of Arkansas

Concordant plutonium/xenon and iodine/xenon decay intervals have been obtained for a dozen meteorites, mostly achondrites. Plutonium-244 and iodine-129 abundances in the early solar system suggest that these extinct nuclides were synthesized in the galactic nucleosynthesis process, which lasted several billion years.

THE study of the extinct nuclides which existed in the early solar system is of great scientific interest, because knowledge of their relative abundances yields a crucial test for or against various theories concerning the galactic synthesis of the chemical elements, and because it enables us to establish a new dating method for the early history of the solar system.

Since the plutonium-244 hypothesis was first presented in 1960 (ref. 1), much experimental evidence in support of the theory has been obtained in this laboratory and elsewhere²⁻⁹. Kuroda et al.⁸ attempted to determine the initial plutonium-244/iodine-129 ratio at the time of cessation of galactic nucleosynthesis assuming that the plutonium/xenon and iodine/xenon decay intervals for several achondrites are concordant at about 300×10^6 yr. Two difficulties arose in this work: (a) some of the achondrites seemed to yield concordant plutonium/xenon and iodine/xenon intervals considerably shorter than 300×10^6 yr, and (b) a number of meteorites (notably chondrites) seemed to contain far greater quantities of excess radiogenic xenon-129.

Kuroda et al.⁸ left (a) unexplained and attempted to explain (b) as resulting from the fact that excess quantities of xenon-129 were produced from iodine-129, which was formed in the solar synthesis process, such as suggested by Fowler et al.^{10,11}.

It is far more difficult to interpret xenon isotope ratio data than to interpret lead isotope ratio data, not only because (i) xenon has nine stable isotopes, while lead has four, and precise measurements of the isotope ratios of the former are much more difficult than for the latter, but also because (ii) the meteoritic xenon isotope abundance ratios are often severely altered by the addition of the isotopes at masses 124, 126, 128, 129, 130, 131 and 132 produced by cosmic rays. The only isotopes of xenon which are not affected by the cosmic-ray irradiation are the isotopes at masses 134 and 136.

The chief difficulties encountered in the previous works were principally caused by (ii), because the xenon isotope ratio data were normalized to xenon-130 and the abundance of this isotope, especially in calcium-rich achondrites, can be quite severely altered by the cosmic-ray irradiations.

In the present work, we have re-examined all the xenon isotope ratio data obtained in this laboratory and elsewhere, and re-calculated the plutonium/xenon and iodine/xenon decay intervals of many achondrites. In this new calculation, we take advantage of the fact that xenon-134 and xenon-136 are the only stable xenon isotopes which remained unaffected under the cosmic-ray irradiations. The initial abundances of the two important extinct nuclides plutonium-244 and iodine-129 at the time of cessation of nucleosynthesis can be determined by this method in a much less cumbersome manner than before. A surprisingly excellent concordancy was obtained between the plutonium/xenon and iodine/xenon decay intervals of about a dozen achondrites studied in this laboratory and elsewhere.

For the plutonium/xenon decay interval, because the production of xenon-134 and xenon-136 caused by cosmic-ray bombardment is negligible, we may write

$${\binom{134 \text{Xe}}{136 \text{Xe}}}_{Met} = {\frac{134 p \text{Xe} + 134 f \text{Xe}}{136 p \text{Xe} + 136 f \text{Xe}}} = m$$
(1)

where superscripts p and f represent primordial and fission components respectively, and subscript Met refers to the meteorite.

We may also write that

$${\binom{134 p \times e}{136 p \times e}} = p \ (= constant)$$
 (2)

We have chosen the Murray carbonaceous chondrite to represent primordial xenon. Because $(^{134}\text{Xe})^{136}\text{Xe})_{\text{Murray}} = 1\cdot19 \simeq 1\cdot18 = (^{134}\text{Xe})^{136}\text{Xe})_{\text{atm}}$, the presence of a slight atmospheric component in the meteoritic xenon will not seriously affect our calculation.

If the fission component is from one single source, namely plutonium-244, then

$$\frac{^{134}fXe}{^{136}fXe} = f \text{ (= constant)}$$
 (3)

From equations (1)-(3) we have

$$\frac{^{136}f\text{Xe}}{^{136}\text{Xe}} = \frac{p-m}{p-f} \tag{4}$$

where ${}^{136}Xe = {}^{136}pXe + {}^{136}fXe$.

If plutonium and uranium were not fractionated in the meteorites, we may write that

$$(^{136f} Xe)_{244} = \alpha \cdot {}^{238} U \cdot \exp(\lambda_{\alpha_{238}} (T + \Xi)) \cdot Y_{136} \cdot \left(\frac{\lambda_f}{\lambda_{\alpha} + \lambda_f}\right)_{244} \cdot \exp(-\lambda_{\alpha_{244}} \Xi)$$

$$(5)$$

where α is the plutonium-244/uranium-238 ratio at the time of cessation of nucleosynthesis; λ_{a238} is the alpha decay constant of uranium-238; T is the age of Earth and meteorites $(4.55 \times 10^9 \text{ yr})^{12}$; Y_{136} is the plutonium-244 spontaneous fission yield for mass chain 136; λ_{a234} and λ_{f244} are the alpha and spontaneous fission decay constants of plutonium-244; and Ξ is the plutonium/xenon decay interval which is the interval between the cessation of nucleosynthesis and formation of the meteoritic body and its subsequent cooling to temperatures at which the meteoritic body could retain xenon (sometimes termed the formation interval).

Because

$$\exp(\lambda_{\alpha_{238}}(T+\Xi)) \simeq \exp(\lambda_{\alpha_{238}}T)$$

we have

$$(^{136}fXe)_{244} = ^{238}U \cdot \exp(-\lambda_{a244}\Xi)$$
 (a constant) (6)

The contribution from the uranium-238 spontaneous fission is

$$(^{136f}\text{Xe})_{238} = ^{238}\text{U} \cdot Y_{136} \cdot \left(\frac{\lambda_f}{\lambda_\alpha + \lambda_f}\right)_{238} \cdot \\ \left[\exp(\lambda_{238}(T + \Xi)) - 1\right] \quad (7)$$

Using $T=4.55\times 10^9$ yr, $Y_{136}=6$ per cent and if $\Xi\cong 3\times 10^8$ yr we obtain

$$\left(\frac{^{136}fX_{\Theta}}{^{238}U}\right)_{238} = 3.1 \times 10^{-6} \text{ cc stp/g of uranium}$$
 (8)

As pointed out by Rowe and Kuroda³, this amounts to approximately one-tenth of that from plutonium-244 spontaneous fission in the case of the meteorite Pasamonte. It follows from equations (4), (5) and (6) that

$$\frac{p-m}{p-f} = \left(\frac{^{236}\text{U}}{^{136}\text{Xe}}\right)_{Met} \cdot \exp(-\lambda_{a224}\Xi) \cdot \text{constant} \quad (9)$$

which means that if (p-m) is plotted against the uranium-238/xenon-136 ratio, a straight line should be obtained for one or more meteorites, which were formed at the same time and the slope should correspond to the value E. Fig. 1 shows such a plot. The results indicate that these meteorites were not formed at the same time, as was previously assumed⁸. It is also clear from Fig. 1 that there exist real differences in the formation interval in the same class of meteorite as well as in different classes This information, when more accurate of meteorites. measurement of gas content, isotope ratios and uranium measurement in the same aliquot are available, could be of vital interest in shedding light on problems of cooling rate, the depth of these meteorites in the parent body and the number of parent bodies.

The absolute value of Ξ for these meteorites cannot be determined until the value of α becomes known, while differences in the values of Ξ for other meteorites relative

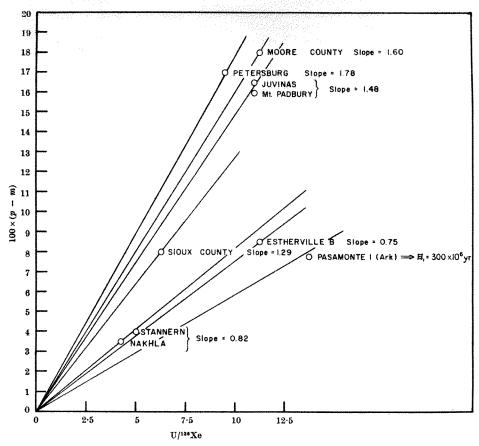

Fig. 1. A plot showing correlation between fission xenon-136 and uranium in various achondrites. The logarithms of slopes have direct proportionality to plutonium/xenon decay interval.

to Pasamonte (or any other meteorite) can be calculated from the slopes in Fig. 1. Let us by way of experiment use the expression for a given by Kuroda² in 1961, for the purpose of calculating tentative values of Ξ :

$$x = \frac{P_{244}}{P_{238}} \cdot \frac{\lambda_{238} - \lambda_{*}}{\lambda_{244} - \lambda_{*}} \cdot \frac{\exp(-\lambda_{*}\Delta) - \exp(-\lambda_{244}\Delta)}{\exp(-\lambda_{*}\Delta) - \exp(-\lambda_{238}\Delta)}$$
(10)

where P_{244} and P_{238} are the production rates of plutonium-244 and uranium-238, respectively, and are assumed to be equal in the r process, λ_* is the rate constant for the nucleosynthesis (the nucleosynthesis rate is assumed to decay exponentially since the mean time of beginning with the decay constant λ_*), and Δ is the duration of nucleosynthesis. Using $\lambda_* = 0.1 \times 10^{-9} \text{ yr}^{-1}$, $\Delta = 6.0 \times 10^9 \text{ yr}$, $\lambda_{238} = 0.154 \times 10^{-9} \text{ yr}^{-1}$ and $\lambda_{244} = 8.45 \times 10^{-9} \text{ yr}^{-1}$, the above equation yields a value of $\alpha = 2.35 \times 10^{-2}$.

In terms of cc str/g of uranium, we now have the plutonium-244 spontaneous fission produced ¹³⁶ Xe

$$\left(\frac{^{136}\text{Y.e}}{\text{U}}\right)_{Met} = 3.2 \times 10^{-4} \exp(-\lambda_{244}\Xi) \text{ (cc stp/g)}$$
 (11)

From equations (5), (8) and (11) we secure a value of $\Xi = 300^{+4}$ million years for Pasamonte. The plutonium/ xenon decay intervals based on this value are tabulated in Table 1.

In the cases of some meteorites (Lafayette, Estherville, Cumberland Falls and Pena Blanca Springs), the values of (p-m) are small, and the calculation of Ξ by this method becomes uncertain. The E values for these meteorites were calculated by the method described by Kuroda et al.8 and are included in Table 1. In calculating the values of Ξ , we estimated ± 30 per cent errors in determining the slopes, most of which are caused by uncertainties in the measurements of total gas contents

($\sim \pm 25$ per cent). This error limit corresponds to an uncertainty in Ξ of +45 and -35×10^6 yr.

The calculation of the iodine/xenon decay intervals is somewhat more complicated as xenon-129 consists of

Pasamonte I (Ark.) Lafayette † Estherville † Cumberland Falls † Pena Blanca Springs †	110 100 30 460 22		315 190 ± 30 × 10 ⁴ yr 280 ± 30 × 10 ⁴ yr 250 ± 30 × 10 ⁵ yr 160 ± 30 × 10 ⁵ yr	280	265	250	245±2

three components: primordial (p), cosmic-ray-produced (c) and radiogenic (r). Fortunately, however, an error by a factor of two introduces an uncertainty of $\pm 17 \times 10^6$ yr in the value of Ξ .

Let
$$(^{134}Xe)^{(130}Xe)_{Obs} = a$$
 $(^{136}Xe)^{(130}Xe)_{Obs} = b$ $(^{134}pXe)^{(130}pXe) = p_1$ $(^{136}pXe)^{(130}pXe) = p_2$ $(^{120}pXe)^{(130}pXe) = p_2$

It follows from equations (1) and (3) that

$${\binom{134 f \text{Xe}}{136 f \text{Xe}}} = f = {\binom{134 \text{Xe} - 134 p \text{Xe}}{136 \text{Xe} - 136 p \text{Xe}}}$$
(13)

From equations (12) and (13) we have

$$\frac{^{130}\text{Xe}}{^{130}p\text{Xe}} = \frac{p_1 - f \cdot p_2}{a - f \cdot b} \tag{14}$$

and

$$\frac{^{1297}\mathrm{Xe} + ^{1296}\mathrm{Xe}}{^{130}p\mathrm{Xe}} = \left(\frac{^{129}\mathrm{Xe}}{^{130}p\mathrm{Xe}}\right)_{Met} - \left(\frac{^{129}\mathrm{Xe}}{^{130}\mathrm{Xe}}\right)_{P} \qquad (15)$$

where superscripts r and c refer to radiogenic and cosmicray-produced components, respectively, and subscripts Met and P refer to the ratios in the meteorites and in the primordial xenon (Murray), respectively.

The cosmic-ray-production ratios 124eXe: 126eXe: 128eXe: 1306Xe have been determined by a number of investigators 5, 5, 9, 12, 13 and are reasonably well known. The relative production ratio, however, for 1226 Xe is unknown, except that Rowell estimated that

$$\frac{^{129}cXe}{^{126}cXe} = x \le 0.84$$

We have used x=1 in our calculations. At f=1.00 we try to show the effect of large variation in x (± 0.4) on Ξ₁₂₉ in Table 2.

The value of f in equation (14) is also unknown. Pepin⁵ calculated the value of f to be 0.98, while according to Hohenberg et al. f = 0.96. Because of this uncertainty we have calculated the values of Ξ for f = 0.95, 0.96, 0.97, 0.98, 0.99 and 1.00. The results are shown in Table 2. In the case of four meteorites (Lafayette, Estherville A, Cumberland Falls, Pena Blanca Springs), Z values were calculated by the method described earlier by Kuroda et al.8.

The initial 120 I/127 I ratio (β) used in the calculation was again taken from the report by Kuroda²

$$\beta = \frac{P_{129}}{P_{127}} \cdot \frac{\lambda_*}{\lambda_{129}} \cdot \frac{1}{\exp(\lambda_* \Delta) - 1}$$
 (16)

Using $\lambda_{129} = 40.3 \times 10^{-9}$ yr⁻¹, $P_{129} = P_{127}$, $\lambda_{*} = 0.1 \times 10^{-9}$ yr⁻¹ and $\Delta = 6.0 \times 10^{9}$ yr, we obtain

$$\beta = 3.0 \times 10^{-3}$$

This gives in terms of cc str/g of iodine

$$\frac{\binom{1297\text{Xe}}{\text{I}}_{\text{Met}}}{1}_{\text{Met}} = 5 \cdot 3 \times 10^{-1} \exp\left(-\lambda_{129}\Xi\right) (\text{ce str/g of iodine})$$
 (17)

The results are plotted in Fig. 2 in such a manner that the mean value of Ξ_{129} obtained from Table 2 is placed on the solid line whose slope corresponds to the iodine-129 half-life (17 million years). The corresponding values of ¹³⁶ Xe/U are plotted vertically above or below the Ξ_{128} points. The dotted line drawn through the values of ¹²⁶fXe/U thus plotted has a slope corresponding to the half-life of 82 million years. Plutonium-244 and the initial value at $\Xi = 0$ corresponds to 3.2×10^{-4} cc str/g.

Fig. 2 shows that the plutonium/xenon and iodine/ xenon decay intervals of these meteorites are concordant within the error limits. It also shows that the cosmological

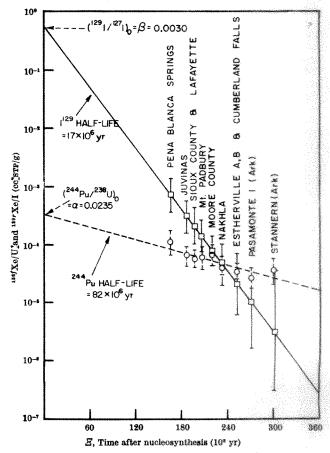

Fig. 2. A comparison of plutonium/xenon and iodine/xenon decay intervals for various meteorites.

^{*} For classification see Table 1.
† Values by Clark et al., see ref 16.
‡ Z₁₂₉ evaluated by method of Kuroda et al.*.

model used in deriving equations (10) and (16) is quite reasonable.

It should be pointed out here that the concordancy cannot be improved much by changing the cosmological model for galactic nucleosynthesis, and a concordancy between the plutonium/xenon and iodine/xenon decay interval cannot be obtained at all if the single event (big bang) model of nucleosynthesis is used.

This investigation was supported by the US Atomic Energy Commission. We thank Dr R. Ganapathy for many helpful discussions and Mr M. G. Myers for help in computer calculations.

Latent Viruses in Chimpanzees with Experimental Kuru

by NANCY G. ROGERS M. BASNIGHT C. J. G'BBS, jun. D. C. GAJDUSEK

National Institute of Neurological Diseases and Blindness, National Institutes of Health, Bethesda, Maryland Forty-seven strains of virus have been isolated from sterile long maintained tissue explants from chimpanzees suffering from experimental kuru. Many are new simian viruses, and none have been demonstrated to be a cause of the kuru syndrome.

The experimental transmission of kuru from humans to chimpanzees1 and the serial transmission of the disease from chimpanzee to chimpanzee² have provided a system from which it is hoped successful isolation of the actiological agent of kuru will be forthcoming. Chimpanzee brain suspension is infectious at 10-5 dilution and the agent is filterable through gradacol membranes of average pore diameter of 220 mu and, in recent experiments, probably 100 mu. The agent is therefore presumably a virus. It is known that the chimpanzee, like other primates, serves as host to endosymbiotic viruses and the presence of such latent agents makes the isolation and identification of the agent causing kuru a difficult problem. The isolation and characterization of a remarkable number of such virusesforty-seven strains so far-from chimpanzee tissues are described here. We have no reason to believe that any of these is aetiologically related to kuru.

The tissues from which these agents were isolated were aseptically removed at autopsy from nine chimpanzees (Pan satyrus) experimentally inoculated with kuru 1-3 yr previously. The chimpanzee virus strains (CV) have been obtained from nine different tissues: brain, spinal cord, kidney, spleen, sympathetic ganglion, optic nerve, lymph nodes, thymus and thyroid. Twelve of the strains were obtained from different areas of the brains of five chimpan-Viruses were recovered using the technique of long term maintenance of tissue fragments in explant cultures and the transfer of undiluted explant fluids to primary human embryo kidney (HEK) cell cultures. Such subculture has usually been carried out when moderate cytopathic effect appeared in the primary explant cultures. Blind passage to HEK cultures of fluids from apparently normal explants, however, has also yielded viruses. In contrast, direct inoculation of suspension of the same chimpanzee brain into many types of tissue cultures, including HEK, has yielded no viruses.

From these virus strains, seven virus types have been differentiated; these have been designated Pan viruses.

The criteria we have used to define a new Pan virus type are: (a) demonstration of antibody to the agent in the serum of the chimpanzee from which isolation was obtained; (b) demonstration of antibody to the agent in the sera of rabbits hyperimmunized with fluids or cells from the HEK cultures; (c) failure of the same immune rabbit sera to neutralize other Pan virus types; and (d) a specific pattern of presence or absence of antibody to the agent unlike that to other Pan virus types in the sera of a large number of chimpanzees from our colony, both kuru-affected and kuru-free.

Eight of these chimpanzees were in advanced kuru disease at the time of death. The disease appeared 11–30 months after inoculation of brain suspension from kuru patients or from chimpanzees with experimental kuru. The ninth animal showed the neuropathological changes observed in kuru³, but was without clinical signs of the kuru syndrome at the time it was killed because of acute gastroenteritis, 10 months after inoculation with brain tissue from a kuru chimpanzee.

In most instances, tissues for explant were obtained within 2 h of death by exsanguination under 'Sernylan' anaesthesia. ('Sernylan': C-395 (phencylidine hydrochloride) or 1-(1-phenylcyclohexyl) piperidine hydrochloride; Parke, Davis and Co.) Representative tissues were removed and dropped immediately into growth medium (Gro-BAF). The vials were then held at room temperature until return to the tissue culture laboratory. (Growth medium was 60 per cent F-10/HAM (ref. 4); 20 per cent foetal calf serum unheated; 10 per cent bovine amniotic fluid; 4 per cent NCTC 109 (ref. 5); 5 per cent Hanks lactalbumin hydrolysate 0.5 per cents; 1 per cent antibiotic mixture and fungizone. The pH of the medium should be 6.6 to 6.8.)

All explants were carried in plastic 30 ml. flasks (Falcon Plastics), incubated at 35° C. Tissues were cut into 0.5–1.0 mm cubes which were then placed in the flasks and spread with the tip of a capillary pipette. Originally the tissue fragments were clotted in place with chick embryo extract

and chicken plasma, but latterly they have been spread in the flask without a clotting matrix. After 1.5-12 h at 35° C, 1.0 ml. of slightly acid growth medium was added. When the longer period of incubation was contemplated, the pieces of tissue were moistened with a few drops of growth medium contained in the tip of the pipette. Flasks were not handled for several days unless, by inspection, the medium had become definitely alkaline. If this occurred, it was gently decanted and replaced with 1.0 ml. of fresh Gro-BAF. Occasionally this was repeated several times. Only rarely did cellular outgrowth occur if the medium remained alkaline. When the fragments were firmly adherent to the flat face of the flask an additional 2.0 ml. of Gro-BAF was added without danger of floating the tissue. Subsequent feedings were in 3.0 ml. volumes. When the outgrowing cells had been well sheeted, the originating tissue fragments usually became detached. A few of these were successfully restarted as late as 42-69 days after the original explant by gently emulsifying them with a pipette and distributing into new flasks.

Outgrowth was usually visible in 4-6 days. Flasks were examined microscopically at weekly intervals and the cultures were fed with Gro-BAF at 10-21 day intervals. At irregular intervals, generally when explant cultures were being fed, subcultures into human embryo kidney cells were made, using the spent fluids and cellular debris as inoculum. Subculturing was, at times, performed in the absence of the cytopathic effect in the explants; in some such cases the effect appeared later, at times even after it had already been noted in the HEK subcultures. No attempt was made to split the explants. Those in which viral cytopathic effect was noted were frozen at -70° C when the effect reached 3+ or 4+, while others are still living after more than a year. From nine explanted tissues of one additional animal, no viral agent has been isolated and seven of the cultures are still surviving after more than a year.

Hyperimmune antisera were prepared for each of the newly isolated viruses in rabbits by intravenous injection

of 1.0 ml. of undiluted tissue culture fluid containing the agent on days 0, 7, 14 and 21. Animals were generally bled out about 14 days after the last dose of antigen, that is, on day 35 of the immunization procedure.

The first thirty-seven viruses isolated are summarized in Table 1, with the day of passage to HEK cell cultures and the day of first appearance of cytopathic effect in both the primary explants (if it occurred) and in the HEK indicator cultures. The appearance of the cytopathic effect of the strains classified thus far and the virus titre attained in HEK cultures on first or second passage are also recorded. Ten additional virus strains from explanted tissue of two chimpanzees (A 14 and A 21) are not included in Table 1, because they were only recently isolated. (All chimpanzee A numbers used in this paper refer to animals previously reported in the literature with summaries of the inocula they received, the incubation periods and the durations of disease2.)

Chimpanzee virus (CV) strains are listed serially in Table 1 in the order of isolation. Each new isolate is immediately given a CV strain designation. Distinct virus types defined from these strains are tentatively called Pan viruses, from the generic name of the chimpanzee, and carry a serial number designation until such time as they are identified with known viruses. Thus, the Pan designation does not designate a new virus type but is our code for successively distinguished viruses that we have found to be latent in the chimpanzee. When each Pan virus is better characterized, it is given an appropriate name in the viral group to which it belongs, or it is identified as a known virus. Thus, Pan 1 has been given the name Simian foamy virus 6, and Pan 2 simian foamy virus 7. Pan 3 is reovirus type 2, and Pan 4 reovirus type 1. Pan 5, 6 and 7 are adenoviruses, but cannot yet be designated by type.

So far, seven chimpanzee virus strains (CV 1, CV 18, CV 30, CV 34, CV 35, CV 36, CV 37) have been designated as Pan 1; five strains (CV 11, CV 12, CV 13, CV 14, CV 16) as Pan 2; two strains (CV 2, CV 4) as Pan 3; and one strain each as Pan 4 (CV 3), Pan 5 (CV 23),

Numbers refer to the experimental animals reported by Gajdusek, Gibbs and Alpers².
 Blanks indicate that explants were observed for over 120 days without showing any CPE; some are still growing.
 Blanks indicate a type of CPE without identifying characteristics.
 Titre expressed as -log₁₀ of that dilution which contains a TCID₅₀/linoculum.

* Titres expressed as the reciprocal of the highest dilution of serum that neutralized 50 to 300 $TCID_{50}$ in HEK cell cultures. Titres less than 10 are indicated by 0, titres \geq 10 are indicated by +.
† Titres expressed as the reciprocal of the highest dilution of serum that inhibited haemagglutination of human group O erythrocytes by about 4 $_{\rm U}$ of antigen. Titres less than 10 are indicated by 0, titres \geq 10 are indicated by +.

Pan 6 (CV 32), and Pan 7 (CV 33). Pan 1 has been isolated from three chimpanzees, whereas Pan 2, the other foamy virus, from only one animal. Three different virus types have been obtained from chimpanzee A 1 (Pan 1, Pan 3 and Pan 4) and from chimpanzee A 16 (Pan 1, Pan 6 and Pan 7).

Table 2 summarizes determinations of neutralizing antibody to Pan viruses 1, 2, 5, 6 and 7, and haemagglutination inhibiting (HAI) antibodies to Pan 3 and 4 in sera from normal and kuru affected chimpanzees, sera from human kuru patients and normal Fore natives in the kuru region, and sera from four hyperimmunized rabbits. Serum from each homologous chimpanzee neutralizes the virus isolated from its tissues: serum from chimpanzee A 1 neutralizes Pan 1 (CV 1); serum from chimpanzee A 2 neutralizes Pan 2 (CV 11). Sera from chimpanzees A 5 and A 16, from which other strains of Pan virus 1 were isolated, also neutralize the CV 1 strain of Pan virus 1, as well as the homologous CV strains isolated from each animal. These chimpanzee sera neutralize only the chimpanzee foamy virus type which their explants yielded. This is fortuitous because sera from kuru affected chimpanzees whose explants yielded no strains of Pan virus 1 or 2 have neutralized one or the other of these viruses, as have sera from some normal chimpanzees. Human kuru patients and normal Fore natives show no antibody to either Pan 1 or Pan 2, but the one patient whose serum was examined more fully shows antibody to Pan 3 (reovirus type 2), Pan 4 (reovirus type 1) and Pan 7 (adenovirus). The four hyperimmune rabbit sera are specific for the immunizing virus. Tests with Pan 5 hyperimmune rabbit serum are incomplete; sera against Pan 4, 6 and 7 are in preparation.

Simian Foamy Viruses from Chimpanzees

Pan viruses 1 and 2 in HEK cell cultures produce a vacuolated syncytium which eventually degenerates and leaves a "moth eaten" appearance. This cytopathic

effect is slow in developing, rarely appearing before 7 days, and is often delayed for 2 to 3 weeks. Tissue culture fluids contain $10^{2.5}$ – $10^{4.5}$ $TCID_{50}/0.1$ ml. of inoculum. Both viruses are stable on storage at -70° C, ether sensitive, inhibited by 5-iodo-deoxyuridine (IUDR), and are inactivated at 56° C in 30 min. No inclusion bodies have been seen.

The ill defined group of simian foamy viruses consists of viruses isolated from monkey or ape tissues which cause giant cell syncytia in tissue culture; produce no demonstrable intracytoplasmic or intranuclear inclusion bodies; have not haemagglutinated test erythrocytes from a wide variety of species, and have not produced clinical disease after inoculation of 1 day old mice or hamsters. The previously defined simian foamy viruses were isolated from cynomolgus (Nos. 1 and 2) (refs. 8 and 9), rhesus (No. 3) (ref. 10), squirrel (No. 4) and Galagos monkeys (No. 5) (personal communication from P. Johnston). The first three have proved to be RNA viruses, whereas the fourth is inhibited by 5-iodo-deoxyuridine.

Pan 1 and Pan 2 fit these criteria well, and so we have assigned them positions as simian foamy virus 6 and 7, respectively, in conferences with Dr Paul Johnston of the Department of Microbiology, University of Louisville Medical Centre. Two strains of Pan virus 1 (that is, CV 1 and CV 18) and one of Pan virus 2 (that is, CV 11) were not neutralized by seven hyperimmune typing sera to the previously described simian foamy viruses: rabbit antiserum to types 1, 2 and 3, obtained from Dr J. A. Morris, of the Division of Biologics Standards, National Institutes of Health, and to types 1, 2, 3 and 4 from Dr Johnston. Our own antisera to Pan viruses 1 and 2, from rabbits hyperimmunized with three injections of HEK fluids at weekly intervals, have shown specific high titre neutralization to the homologous virus type without cross neutralization between the two types (Table 3). Typing sera from these two viruses are now being prepared in horses in the Simian Foamy Virus Typing Programme in Dr Johnston's laboratory. Cabasso¹⁰ has now identified an eighth agent fitting the criteria of this undoubtedly heterogeneous group.

Reoviruses from Chimpanzees

Pan viruses 3 and 4 in HEK cell culture fluids have haemagglutinated human group O erythrocytes to titres of 1:128. They produce a reovirus-like cytopathic effect in HEK in 3 to 4 days and infectivity titres of 105.3 to $10^{6.5}~TCID_{50}/0\cdot1$ ml. in 2 weeks. Specific typing sera against reoviruses 1, 2 and 3 have been used in haemagglutination inhibition tests with these agents. (Hyperimmunized rooster sera were obtained from the Communicable Disease Center, Atlanta, Georgia.)

Haemagglutination of each of two Pan 3 isolates (CV 2 and CV 4) was strongly inhibited by reovirus antiserum to titres of > 640 and 640, respectively. Both exhibited minimal crossing with reovirus type 1 (titres of 40 and 10, respectively). Haemagglutination of Pan virus 4 (CV 3) was inhibited by reovirus 1 antiserum at a dilution greater than 1:5,120 (crossing at a dilution of 1:10 with reovirus 2). It is noteworthy that Pan viruses 3 and 4 were isolated from different areas of the brain of the same chimpanzee (A 1; see Table 1). The sera of all the chimpanzees thus far tested have shown HAI antibody to both Pan 3 and Pan 4, with the exception of the sera from chimpanzee A 4 which failed to react with Pan 3

and showed minimal inhibition with Pan 4. The serum of a single kuru patient reacted with both. Considering the ubiquity of reoviruses, these last reactions are scarcely surprising.

Adenoviruses from Chimpanzees

Pan 5, 6 and 7 viruses, in HEK cell culture, originally were thought to be enterovirus like, but as cytopathic effect markedly increased, their adenovirus nature was indicated. This was confirmed by complement fixation, through the kindness of Dr Wallace Rowe (National Institutes of Health, Bethesda, Maryland), who has shown that these three viruses are not neutralized by antisera to human adenoviruses types 1 to 31, inclusive, yet they produce antigens in $H\tilde{E}K$ cell cultures which react to high titres with human adenovirus convalescent sera. As yet, they have not been identified as to type; they are not neutralized by antisera to the seventeen simian reoviruses, SV 1, 11, 15, 17, 20, 23, 25, 27, 30-34, 36-38. Screening neutralization tests, however, using many chimpanzee and hyperimmune rabbit sera indicate their dissimilarity, as illustrated by these three sera selected from Table 2.

Virus	Hyperimmune rabbit, Pan 5	Pre-bleed chimp, 35	Pre-bleed chimp, 33
Pan 5	+	+	+
6	0	0	+
7	0	+	+

The remaining virus strains shown in Table 1, as well as at least ten others from the two chimpanzees not included therein, are still under investigation. doubtedly, many will fall into the groups described above.

The significance of these results lies in the demonstration of a wide range of latent viruses, often two or more in a single animal, in tissues that are sterile by conventional techniques of virus isolation. These techniques have at times included inoculation of a 10 per cent suspension of various organs into different tissue cultures (HEK, BS-C-1, HEp_2 , green monkey kidney, and so on). Were monkey kidney, rather than HEK, cell cultures used as an indicator system for the explant viruses, many more agents might well have been isolated. internal milieu of an animal cannot be regarded as microbiologically sterile even in the case of such organs as the brain and spinal cord. The many viruses isolated from human adenoid tissue^{11,12} and the latency of herpes simplex virus are long familiar evidence in this direction. That many viruses are commonly latent in normal tissues has been known from the large number of simian viruses isolated from rhesus monkey kidney tissue cultures used in the cultivation of poliovirus for vaccine production¹³. The demonstration of viruses in germ free mice further supports this view¹⁴⁻¹⁶. Furthermore, a herpeslike virus has been demonstrated17 in, and a reovirus isolated18 from, long maintained explants of Burkitt lymphoma, and the maedi virus has been isolated from explants of sheep lung19.

The problem this profusion of chimpanzee virus strains poses in attempting to find the agent responsible for kuru is immense. So far, only one of the new viruses, the CV 11 strain of Pan 2, has been reinoculated into a chimpanzee intracerebrally after three serial cell culture passages at terminal dilution, with a final dilution factor of 10-13. Unfortunately, this animal was found dead 11 months after inoculation. Although explants were attempted, post-mortem bacterial invasion was so extensive that only a few grew. No viral agent has as yet been isolated from the few surviving explants. We are now trying to circumvent partially the problem of differentiating these numerous endosymbiotic viruses in the chimpanzee from a possible kuru agent by obtaining explants directly from human patients at lymph node biopsy or at early autopsy.

Although the few explants of tissue of kuru patients already in cultivation have not as yet yielded any agents. we have at present under study several unidentified agents from explants obtained from other human chronic neurological disorders.

Stimulation of Biosynthesis of Glyceride

by

G. HÜBSCHER

D. N. BRINDLEY

M. E. SMITH

B. SEDGWICK

Department of Medical Biochemistry, University of Birmingham

The biosynthesis of glycerides from glycerolphosphate and palmitate, catalysed by mitochondrial and microsomal fractions, is greatly stimulated by the supernatant fraction (6,000,000 \times g-min). This is caused by the presence of a specific phosphatidate phosphohydrolase. unsaturated long-chain fatty acids and unspecific protein(s) in the supernatant fraction.

THE biosynthesis of triglycerides may proceed by two pathways-a monoglyceride pathway and a glycerolphosphate pathway—according to the glyceride glycerol precursor utilized (see Fig. 1). The individual enzymes catalysing these biosyntheses have been reported to be located in particulate subcellular structures1-16. Ten years

ago, however, Shapiro et al.17,18 observed that the biosynthesis of glycerides by the glycerolphosphate pathway catalysed by a mitochondrial fraction from rat liver was greatly stimulated by a supernatant fraction. observation has since been confirmed and extended in several laboratories; the stimulation of glyceride bio-

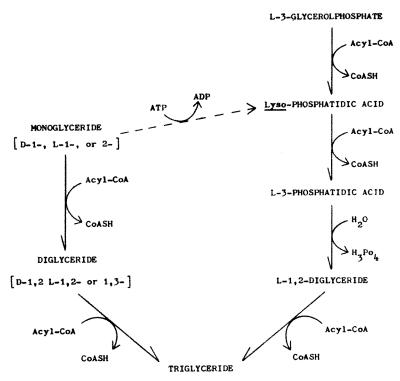

Fig. 1. Pathways in glyceride biosynthesis.

synthesis by the particle free supernatant (6,000,000g)has been observed with mitochondrial and microsomal fractions prepared from various tissues10,15,19-23. example of this supernatant stimulation is given in Table 1, which also shows that the active principles consist of a heat-stable and a heat-labile factor. The occurrence of two factors was discovered by Shapiro et al.18, who pointed out that the heat-stable factor could be partly extracted with ethanol-ether. Lately, detailed investigations of the heat-labile principle showed it to consist of more than one factor. Because these observa-tions are widely dispersed in the literature it seems appropriate to survey this particular aspect of glyceride biosynthesis. In this article we discuss the function and nature of the various factors present in the supernatant fraction in relation to the biosynthesis of glycerides by the glycerolphosphate pathway. The formation of glycerides by the monoglyceride pathway is not stimulated by the supernatant fraction.

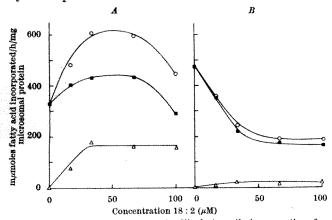

Fig. 2. Effect of increasing amounts of linoleate on the incorporation of palmitate into glycerides using a microsomal fraction from cat intestinal mucosa. The assay system was that described in Table 2 except that the concentration of linoleate was varied as indicated. The assay system contained 0.6 mg of microsomal protein and 2.4 mg of protein of an acetone-treated supernatant preparation. A, Fatty acids incorporated into glycerides: and B, fatty acids incorporated into phosphatidate.

\$\triangle \triangle \

The Heat-stable Factor

A clue to the nature and function of the heat-stable factor was obtained in investigations of the effect of unsaturated long-chain fatty acids on the formation of glycerides from glycerolphosphate and palmitate24. Palmitoleic, oleic, linoleic and linolenic acid were found to stimulate the incorporation of palmitate and were themselves incorporated. This is shown in Fig. 2 with sub-cellular preparations from the mucosa of cat small intestine. At optimum concentrations of linoleate, the molar ratio palmitate: linoleate present in the glyceride fraction—more than 80 per cent triglycerides—was 2.6, indicating that mixed acid triglycerides may have been formed. Fig. 2 also shows the amounts of labelled acids present in phosphatidate. These decreased with increasing concentrations of linoleate in the assay system and it is interesting that the molar ratio of palmitate: linoleate was > 10. This may indicate that intermediates containing linoleate were preferentially incorporated into glycerides. For example, phosphatidate phosphohydrolase may act preferentially on a phosphatidate containing palmitate and linoleate compared with one containing only palmitate.

The synergistic action of palmitate and unsaturated long-chain fatty acids was not observed when mixing palmitate with saturated long-chain fatty acids nor was

it seen when the formation of triglycerides by the mono-

glyceride pathway was studied24.

Thus we concluded that if the heat-stable factor of the supernatant fraction involves unsaturated long-chain fatty acids, these acids ought to occur in appropriate amounts in the supernatant fraction, and furthermore their removal from the supernatant fraction ought to reduce its stimulating activity. Both these assumptions were proved to be correct²⁴. The supernatant fraction was found to contain up to 25 mumoles of free fatty acids/mg of protein of which about 43 per cent was unsaturated C₁₈-acids. The removal of all lipids including free fatty acids from the supernatant fraction by treatment with acetone resulted in a decreased stimulating activity (Table 2). When small concentrations of linoleate were added to a supernatant treated with acetone, the stimulating activity was restored to the level obtained with the same but untreated supernatant preparation. Although unsaturated fatty acids are a heat-stable factor it cannot be excluded at this stage that an unspecific protein in fatty acid free supernatant preparations is also heat stable and thus contributes to the overall stimulation of glyceride biosynthesis. The effects of unsaturated fatty acids are small when compared with those of the whole supernatant fraction. Nevertheless, the increased rate of formation of triglycerides from a mixture of palmitate

STIMULATION OF GLYCRRIDE BIOSYNTHESIS BY SUPBRIATANT INS USING A MITOCHONDRIAL FRACTION FROM RAT LIVER

Addition of protein	mµmoles of palmitate incorporated into glycerides
None	11
Boiled supernatant fraction (11.8 mg)	$\begin{smallmatrix}13\\311\end{smallmatrix}$
Supernatant preparation (0.9 mg)	
Supernatant preparation (0.9 mg) + boiled supernatan fraction (11.8 mg)	1t 474

The assay system contained, in a final volume of 3 ml., 16·6 mmolar Sörensen phosphate buffer, pH 7·4, 6·6 mmolar ATP, 0·033 mmolar CoA, 20 mmolar D.1-3-glycerolphosphate, 6·6 mmolar potassium fluoride, 2·25 mmolar reduced glutathione, 0·8 mmolar palmitate and 3·6 mg of mitochondrial protein. Incubation lasted 40 min at 37° C. Supernatant preparations were obtained from rat liver. Boiled supernatant fraction was the supernatant fraction (6.000,000 × g-min) heated for 3 min at 100° C. Supernatant preparation was 0-45 per cent ammonium sulphate precipitate of the supernatant fraction (6.000,000 × g-min).

Table 2. REFECT OF LINOLEATE AND OF DEFATTED SUPERNATANT PREPARA-TIONS ON THE INCORPORATION OF PALMITATE INTO GLYCERIDES USING A MICROSOMAL FRACTION FROM THE MUCOSA OF CAT SMALL INTESTINE

Additions	mµmoles of palmit incorporated into glycerides
None	25
Supernatant preparation (1.2 mg)	111
Supernatant preparation (1.2 mg) + linoleate (67 µmolar)	144
Defatted supernatant preparation (1.2 mg)	84
Defatted supernatant preparation (1.2 mg) + linoleate (67 \(\mu\text{molar}\))	149

The assay system contained, in a final volume of 3 ml., 16.6 mmolar potassium phosphate buffer, pH 7.4, 6.6 mmolar ATP, 0.083 mmolar CoA, 3.3 mmolar D.L.3-glycerolphosphate, 13.3 mmolar potassium chloride, 2.7 mmolar reduced glutathione, 1.2 mmolar palmitate and 0.9 mg of microsomal protein. Incubation was carried out for 20 min at 37° C. All supernatant preparations were obtained from the mucosa of cat small intestine. Supernatant preparations were obtained from the mucosa of cat small intestine. Supernatant preparation was 0.50 per cent ammonium sulphate precipitate of the supernatant fraction (6,000,000g). Defatted supernatant preparation was the same supernatant preparation which had been treated with nine volumes of acetone at 0° C to remove all free fatty acids**.

Table 3. STIMULATION OF MITOCHONDRIAL GLYCERIDE BIOSYNTHESIS BY VARIOUS PROTEIN PREPARATIONS

Addition of protein	mμmoles of palmitate incorporated into glycerides
None	19
Defatted bovine serum albumin (25.0 mg)	53
Rat serum (21.5 mg)	45
Lipoprotein-rich fraction from rat serum (4.8 mg)	74
Supernatant preparation (3.9 mg)	260

Assay system was that described in Table 1. The mitochondrial fraction and the supernatant preparation (Table 1) were obtained from rat liver. Other additions were made as indicated. Each protein concentration noted was that giving maximum stimulation.

and linoleate compared with that from palmitate alone points to a fatty acid specificity of one (or more) of the enzyme(s) participating in the formation of triglycerides by the glycerolphosphate pathway, although previous investigations of the enzymes synthesizing phosphatidate using a mixture of stearoyl-CoA and lineloyl-CoA failed to show a definite fatty acid specificity with respect to saturated and unsaturated long-chain fatty acids²⁵. These enzymes were shown, however, to have a preference for long-chain fatty acids^{2,26}. Finally, as the concentrations of unsaturated fatty acids which same order as those found in the cell, this stimulation may have physiological implications. It has been shown that unsaturated fatty acids can stimulate the absorption of saturated acids by the small intestine²⁷.

The Heat-labile Factors

1. Nature and specificity. The heat-labile factors present in the supernatant fraction $(6,000,000 \times g\text{-min})$ are inactivated by heating for 3 min at 70° C and can be precipitated by ammonium sulphate with complete recovery and between three and six fold purification²⁰. When treated with papain, the supernatant fraction loses its activity and gel filtration on 'Sephadex G-200' shows that the minimum molecular weight of the heat-labile supernatant factor(s) is 200,000 (ref. 20). These results clearly indicate the protein nature of the active principles involved.

As glyceride biosynthesis is usually measured by incubating glycerolphosphate and a particulate subcellular fraction with either palmitoyl-CoA or palmitate, the known inhibitory effects of palmitoyl-CoA and free fatty acids on various enzyme systems should be considered. These inhibitory effects can be alleviated by adding protein and in particular albumin to the assay system. Consequently, the heat-labile principle in the supernatant fraction might exert its effect merely by acting similarly to albumin, and there are reports that albumin, various lipoprotein fractions or a boiled microsomal fraction will enhance the formation of glycerides^{8,20,28} or phospha-The stimulating activity of these proteins is low compared with that of the supernatant fraction 20 (Table 3). The stimulating effect of albumin (or lipoprotein) and of low concentrations of the supernatant fraction is, in some instances, additive, but at high concentrations of supernatant fraction the stimulating

effect of albumin or lipoproteins is strongly reduced or absent. The stimulation by lipoproteins decreased when they were defatted²⁸ and so it is possible that at least part of the stimulation caused by native lipoproteins results from the presence of unsaturated fatty acids in these proteins.

Thus the heat labile factors of the supernatant fraction are proteins and only a small portion of the overall stimulation of glyceride biosynthesis caused by the supernatant fraction can be ascribed to unspecific (non-enzyme)

2. The role of phosphatidate phosphohydrolase. Phosphatidate phosphohydrolase has been known for many years³⁰ as has its occurrence in particulate subcellular fractions^{4,6,11,16}. It was usually assumed that the phosphohydrolase located in mitochondrial and microsomal fractions was the enzyme involved in the biosynthesis of complex lipids. The observations described below, which were made independently in two laboratories^{23,31}, throw great doubt on this assumption and point to the involvement of a soluble phosphatidate phosphohydrolase in glyceride biosynthesis.

Analysis of the intermediates and products formed during glyceride biosynthesis in mitochondrial preparations showed that in the absence of the supernatant fraction, most of the label incorporated into total lipids was recovered in phosphatidate³¹ (Fig. 3). When the supernatant fraction was added, the amount of labelled palmitate found in glycerides increased sharply while that found in phosphatidate decreased. Fluoride is known to inhibit phosphatidate phosphohydrolase activity*,** and so it was omitted from the assay system (Fig. 3). The degree of the shift from phosphatidate to glycerides with respect to the amounts of labelled palmitate found in these two lipids at the end of the incubation depended on the amount of supernatant protein addeds. With some preparations, however, a slight increase in the amounts of palmitate in phosphatidate was observed at low concen-

The effect of the supernatant fraction was thus similar to that observed with unsaturated fatty acids except that the magnitude of stimulation of glyceride formation was far greater (compare Figs. 2 and 3). It was therefore essential to exclude the concomitant effect of unsaturated long chain fatty acids. This was done by using a supernatant preparation treated with acetone and free from fatty acids (Table 4). Heating the treated supernatant preparation completely abolished the stimulation of

trations of supernatant fraction.

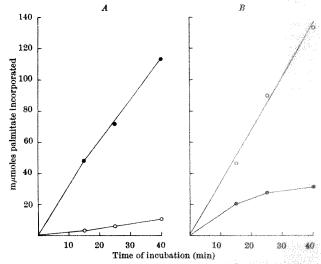

Fig. 3. The incorporation of palmitate into phosphatidate and giverides as a function of time using a mitochondrial preparation from rat liver. The assay system was that described in Table 1 except that potassium fluoride was omitted. A, 4.0 mg of mitochondrial protein; B, 4.0 mg of mitochondrial protein; B, 4.0 mg of mitochondrial protein +6.0 mg of protein of an ammonium sulphate precipitate of the supernatant fraction. • 1.00-palmitate incorporated into phosphatidate, and O, into giverids.

Table 4. EF EFFECT OF DEFATTED SUPERNATANT PREPARATIONS ON INCOR-OF PALMITATE INTO PHOSPHATIDATE AND GLYCHRIDES USING A MITOCHONDRIAL FRACTION FROM RAT LIVER

(3·4 mg) Defatted bovine serum albumin (3·1 mg)	330 329	13 11	343 340

Assay system was that described in Table 1. Supernatant preparations were obtained from rat liver. Defatted supernatant preparation was 0-45 per cent ammonium sulphate precipitate of the supernatant fraction (6,000,000 × g-min) treated with nine volumes of acetone at 0° C to remove all free fatty acids. Boiled defatted supernatant preparation was the same preparation heated for 3 min at 100° C.

glyceride formation, whereas the incorporation of palmitate into phosphatidate was increased to the same extent as that obtained with defatted albumin.

The results so far presented indicate that the supernatant fraction contained either phosphatidate phosphohydrolase activity or a protein which stimulated the mitochondrial phosphatidate phosphohydrolase. Table 5 shows that the first assumption is correct because heating the mitochondrial fraction did not decrease the formation of diglyceride. The substrate used in this experiment was labelled membrane-bound phosphatidate, which had been formed biosynthetically and freed from ATP and other cofactors by centrifugation through a sucrose density gradient³¹. It is interesting that there was very little hydrolysis of phosphatidate when the mitochondrial membrane fraction containing tightly bound phosphatidate was incubated in the absence of the supernatant fraction; this indicates that the phosphatidate phosphohydrolase present in the mitochondrial membrane preparation acted only slowly on the internal substrate.

Table 5. HYDROLYSIS OF MEMBRANE-BOUND PHOSPHATIDATE

Additions	 - Δ mµmoles of palmitate in phosphatidate 	+ Δ mμmoles of palmitate in glycerides
Membrane preparation + supernatant prepa-	6.8	< 2.0
ration Boiled membrane preparation + supernatant	47.8	83.4
preparation	63.0	58-4
Membrane preparation + boiled supernatant preparation	< 2.0	< 2.0

The preparation of the membrane-bound phosphatidate (membrane preparation) is indicated in the text. The membrane preparation (7.0 mg of protein) was incubated in a final volume of 2.0 ml. with 22 mmolar phosphate buffer, pH 7.4 and, where indicated, the supernatant preparation (9.9 mg of protein) for 10 min at 37° C. The supernatant preparation was 0-45 per cent ammonium sulphate precipitate of the supernatant fraction (6,000,000 × g-min). Boiled preparations were heated for 3 min at 100° C.

Phosphatidate phosphohydrolase is usually assayed with aqueous dispersions of phosphatidate and under these conditions the mitochendrial (or microsomal) phosphatidate phosphohydrolase is more active than the phosphatidate phosphohydrolase of the supernatant fraction (Table 6). The reverse is true, however, when membrane-bound phosphatidate is used as substrate. Of all the combinations recorded in Table 6, the supernatant fraction and membrane-bound phosphatidate gave the fastest reaction rate. Addition of freshly prepared mitochondrial fraction to membrane-bound phosphatidate did not bring about a hydrolysis of phosphatidate.

Although the results presented here refer to mitochondrial membranes, the same observations have been

Table 6. HYDROLYSIS OF MEMBRANE-BOUND PHOSPHATIDATE AND OF AQUEOUS DISPERSIONS OF PHOSPHATIDE

Membrane-bound phosphatidate was prepared as indicated in the test. Stable aqueous dispersions were prepared with phosphatidate obtained from egg phosphatidylcholine by enzyme hydrolysis. Each of the above combinations was assayed in slightly different conditions to obtain optimum reaction rates²¹. rates²¹.

* The mitochondrial enzyme was acting on the internal substrate.

made with microsomal fractions^{23,31}. Using either subcellular fraction, the phosphatidate phosphohydrolase activity of the supernatant fraction accounted for most of the stimulation of glyceride formation caused by the supernatant fraction.

If the phosphatidate phosphohydrolase of the supernatant fraction is involved in the biosynthesis of glycerides, it is surprising that of five enzymes participating in this biosynthesis, the phosphohydrolase is the only one found in the cell sap. Mitochondrial fractions prepared under mild conditions in 0.88 molar sucrose instead of the usual 0.3 molar sucrose still showed the same requirement for the supernatant fraction to form maximum amounts of glyceride. Furthermore, a supernatant fraction prepared in 0.88 molar sucrose had the same specific activity with respect to the hydrolysis of membrane-bound phosphatidate as a supernatant fraction prepared in 0.3 molar sucrose. Thus the primary subcellular localization of the enzyme hydrolysing the membrane-bound phosphatidate formed as an intermediate in the biosynthesis of complex lipids remains an open question. If, in the intact cell, this enzyme is bound to mitochondria and the membranes of the endoplasmic reticulum, its linkage is extremely weak.

 ${\bf 3.} \quad \textit{Further factors.} \quad \textbf{Although the presence of phosphati-}$ date phosphohydrolase activity, unsaturated long-chain fatty acids, and unspecific protein(s) in the supernatant fraction account for most of the stimulating activity, there is evidence suggesting that the supernatant fraction contains other stimulating factors.

Studies of the requirement for substrates and cofactors (glycerol phosphate, ATP, CoA and MgCl₂) showed that not even a small portion of the stimulation of glyceride formation by the supernatant fraction could be caused by the presence of any of the known cofactors in this frac-When assaying acyl-CoA synthetase or the synthesis of phosphatidate, however, small but significant stimulations were observed with supernatant preparations.

Using palmitate as substrate the mitochondrial acyl-CoA synthetase reaction was stimulated by 25-35 per cent on addition of 0.5 mg of protein of a supernatant preparation²⁰ (Table 7). For comparison, the data of Farstad, Bremer and Norum³³ are included which were obtained with a microsomal fraction from rat liver. While the exact mechanism of this stimulation is not fully understood, preliminary evidence suggests that the supernatant fraction contains an acyl-CoA synthetase kinase³⁴ the action of which might resemble that of the phosphorylase b kinase³⁵. The observations of Bar-Tana and Shapiro³⁶ may be relevant in this connexion. They found that the first part-reaction of a microsomal acyl-CoA

Assay system contained, in a final volume of 1.0 ml., 16.6 mmolar potassium phosphate buffer, pH 7.4, 3.3 mmolar ATP, 0.033 mmolar CoA, 8.6 mmolar L-3-glycerolphosphate (1 μ c./18.7 μ moles), 13.3 mmolar magnesium chloride, 50 mmolar potassium fluoride, 0.4 mmolar palmitate, 2.6 mmolar reduced glutathione and 1.0 mg of mitochondrial protein. Incubation was for 30 min. at 37° C. Supernatant preparation was 0.45 per cent ammonium sulphate precipitate of the supernatant fraction (6,000,000 × g-min). Boiled supernatant preparation was the same preparation heated for 3 min at 100° C.

synthetase required CoA and that the overall reaction rate of this enzyme was increased by preincubation in the presence of ATP and CoA. From this they decided that the active form of the acyl-CoA synthetase contains enzyme-bound CoA.

Finally, when assaying the biosynthesis of phosphatidate in the presence of high concentrations of potassium fluoride (50 mmolar) to inhibit all phosphatidate phosphohydrolase activity, we found a further small stimulation on adding a supernatant preparation (Table 8). stimulation was heat-stable, an observation already noted in the experiment quoted in Table 4. In that experiment an acetone-treated supernatant preparation was used, and so the heat stable stimulation quoted in Table 8 could not have been caused by unsaturated fatty acids. This observation agrees with those of Lands and Hart29, who reported an increased phosphatidate formation on addition of albumin or a boiled microsomal fraction. The mechanism of this stimulation is unknown but the participation of an acyl carrier protein similar to that studied with preparations from E. coli³⁷ or Cl. butyricum³⁸ cannot be excluded.

This work was supported by grants from the Medical Research Council. We thank Miss Linda Davies for technical assistance.

Model for Origin of Monosaccharides

by NORMAN W. GABEL* CYRIL PONNAMPERUMA Exobiology Division, Ames Research Center, NASA, Moffett Field, California 94035

Formaldehyde, alumina and two naturally occurring aluminosilicates, kaolinite and illite, were refluxed with an aqueous solution of formaldehyde. Formaldehyde was converted to monosaccharides. This provides the basis for a model for the primordial origin of monosaccharides.

In 1861 Butlerow demonstrated that formaldehyde could be converted into a mixture of monosaccharides when heated in aqueous alkaline solution. Others²⁻⁸ have studied extensively the base-induced condensations of formaldehyde. All these experiments involved strongly alkaline media using relatively high concentrations of formaldehyde.

The opinion that because formaldehyde is readily converted to sugars it can be regarded as a primordial precursor of sugars is strengthened by the observation that formaldehyde is one of the products formed when a mixture of methane, ammonia and water, the presumed primitive atmosphere of the Earth, is exposed to either an electric discharge or ionizing radiation 10,11. Further evidence in favour of formaldehyde as a possible intermediate in primitive sugar synthesis comes from the observation that several sugars, including ribose and deoxyribose, are formed by the action of ultraviolet light on a dilute solution of formaldehyde12.

* Present address: Research Laboratories, Illinois State Psychiatric Institute, 1601 West Taylor Street, Chicago.

Some objections have been made to the general acceptance of formaldehyde as a precursor of sugars on the prebiotic Earth. Horowitz and Miller 13 objected to the high concentrations of formaldehyde used in some of the base-induced condensations of formaldehyde as unrealistic in primordial conditions. Abelson¹⁴ maintains that large bodies of water on the Earth were never highly alkaline and that the pH of the oceans has remained fairly constant. A serious difficulty arises because in the absence of an inhibitor, such as an alcohol, formaldehyde rapidly forms paraformaldehyde at moderate temperatures. If ammonia was abundant in the early atmosphere of the Earth, the highly stable compound, hexamethylenetetramine, would also be expected to be the predominant product of formaldehyde condensations.

For these reasons it was decided to examine the possible polymerization of formaldehyde by the action of boiling water in the presence of clay. In these conditions, paraformaldehyde would depolymerize, and there would be a minimum amount of dissolved ammonia present. Such a situation may reproduce more faithfully prebiological

conditions which could have occurred at hydrothermal springs. The microcrystalline aluminosilicate minerals are considered to have -0.66 equivalents of negative charge/unit cell¹⁵, and so they would probably be capable of inducing the condensation of formaldehyde to sugars.

The alumina, chromatography grade, was obtained from the J. T. Baker Chemical Company. The clay minerals were obtained from Ward's Natural Science Establishment and were classified as Kaolinite No. 17 from Lewiston, Montana, and Illite No. 35 from Fithian, Illinois. Kaolinites have the approximate empirical formula (OH)₈Si₄Al₄O₁₀ and illites have the formula

$${\rm (OH)_4} K_{1^-1\cdot 5} ({\rm Si_{6\cdot 5-7}Al_{1^-1\cdot 5}}) \ ({\rm Al_4Fe_4} Mg_4) {\rm O_{20}}$$

In addition, kaolinite is composed of a single silica tetrahedral sheet and a single alumina octahedral sheet, whereas illite has two silica tetrahedral sheets with a central alumina octahedral sheet¹⁵.

In preliminary qualitative experiments, 50 ml. of a 0.33 molar solution of aqueous formaldehyde was refluxed with a suspension of 10 g of either alumina or one of the two samples of aluminosilicate. After an arbitrary refluxing period of 5 h, the suspended material was removed by either filtration or centrifugation and the clear solution was evaporated at reduced pressure to a syrup. The mixture was separated by paper chromatography with butanol: ethanol: water (4:1:1 by volume) in one direction and butanol: pyridine: water (9:5:8 by volume) in the other. The sugars were located on the chromatogram by spraying with aniline hydrogen phthalate¹⁶. The groups of sugars were identified as hexoses, pentoses, tetroses and trioses by comparing their colour reaction with aniline hydrogen phthalate and the R_F values with those of standard monosaccharides. At this concentration of formaldehyde, hexoses were detected only by prolonged refluxing in an inert atmosphere.

In a control experiment, samples of the aluminosilicate minerals were subjected to extraction with boiling water for 5 h. No sugars were detected in the extracts. Siurries of alumina, kaolinite and illite in water exhibited a pH

of 7.4, 4.2 and 5.9, respectively.

A quantitative measure of the conversion of formaldehyde to carbohydrates was carried out by adding 0.1 mc. of ¹⁴C-formaldehyde to the 0.33 molar aqueous formaldehyde solution. Duplicate samples were chromatographed on thin-layer cellulose plates with butanol: pyridine: water (9:5:8) and butanol: ethyl acetate: water (7:1: 2). The radioactive areas were determined by autoradiography, after which the principal radioactive areas were removed from one of the plates. The activity of the individual areas was compared with the total amount of radioactive material applied to the plate. The areas were then identified by spraying the duplicate plate with aniline hydrogen phthalate. The alumina-induced condensation reaction yielded 22 per cent pentoses, 17 per cent tetroses and 38 per cent trioses plus glycolaldehyde. A similar experiment, substituting kaolinite for alumina, produced $3 \cdot \hat{0}$ per cent pentoses and $3 \cdot 9$ per cent tetroses and smaller units. Increasing the refluxing time to 24 h did not appreciably change the yields of monosaccharides (Table 1).

In an attempt to determine the lowest concentration of formaldehyde at which a detectable amount of monosaccharides would still be formed, the previously described condensation reactions were carried out at formaldehyde concentrations of 10^{-3} molar and 10^{-2} molar. A mixture

Table 1 Experiment 1 Alumina Experiment 2 Kaolinite Concentration of formaldehyde 0.33 M 10-8 M 0.33 M 10-4 M per cent Hexoses 3.3 Pentoses 3.0 Tetroses Trioses 3.9

of 0·2 ml. of 10⁻² molar formaldehyde (0·025 mc.), 1·8 ml. of water and 0·5 g of alumina was refluxed under an inert atmosphere for 5 h. The solution was concentrated and chromatographed with a mixture of monosaccharide standards. An autoradiograph was compared with the chromatogram after it had been sprayed with aniline hydrogen phthalate. Glycolaldehyde seemed to be formed but no other sugars were present. Most of the radioactive material remained near the origin. Prolonged refluxing resulted only in the disappearance of the glycolaldehyde.

In a second series of experiments, 0·1 mc. of ¹⁴C-form-aldehyde (0·79 ml. of 10^{-2} molar) was added to 10 ml. of 10^{-2} molar formaldehyde and 2 g of alumina. After refluxing for 5 h, the solution was concentrated and thin-layer chromatography was used again. The conversion to pentoses was 2·3 per cent and the combined conversion to tetroses and tioses was 2·4 per cent. It is surprising, in view of the results at higher concentrations, that there was a yield of 4·0 per cent hexoses. When kaolinite was substituted for alumina 3·3 per cent hexoses, 3·0 per cent pentoses and 4·4 per cent tetroses and trioses were produced. Refluxing for 24 h in an inert atmosphere resulted in a decreased yield of monosaccharides. As in previous experiments, most of the radioactive material remained near the origin.

Using the procedure of Mills¹⁷, ribose was electrophoretically separated from the pentose fraction produced from a 0·33 molar radioactive formaldehyde solution refluxed with alumina. In these conditions the total conversion of formaldehyde to ribose was 3·8 per cent. The results obtained with illite were similar to those found with kaolinite and no quantitative determinations were made.

Since the middle of the nineteenth century, it has been known that aqueous formaldehyde will undergo condensation to a mixture of sugars in the presence of alkali. It has been observed that for this reaction polyvalent and divalent bases serve as better catalysts than mono-Tetramethylammonium hydroxide is valent bases. completely devoid of catalytic activity¹⁸. It has also been observed that the initial rate of condensation is slow; that is, there appears to be what has been called by some investigators^{7,8} a "lag phase" followed by a much more rapid rate of reaction. This "lag phase" was found to be eliminated by the addition of small amounts of glyceraldehyde or dihydroxyacetone^{7,8,18}. These observations can be rationalized by recognizing that there are two distinct reactions involved in the condensation of formaldehyde to the sugar mixture.

It is obvious that the first condensation to occur is that of two molecules of formaldehyde to form glycolaldehyde. Further reactions of the glycolaldehyde with formaldehyde can then proceed through aldol-type condensations and enolizations to yield the sugar mixture. The first reaction, however, implies that the carbon atom of a molecule of formaldehyde must become a nucleophilic centre in order to attack the carbon atom of a second molecule of formaldehyde.

Formaldehyde exists primarily as its hydrate in aqueous solutions (ref. 19 and (1)). The two oxygen atoms would exert an inductive effect on the carbon atom, decreasing

its electron density and thereby stabilizing the anion which would result from the ionization of a proton

attached to carbon. Co-ordination of the oxygens with divalent cations (2) would greatly enhance this effect, which would explain in part the greater efficacy of divalent oxides as catalysts. It should be noted that the

microcrystalline clay minerals usually have alkaline earths, alkali metals and protons adsorbed as cations on their surfaces15. Franzen and Hauck20 have reported that alkaline earth cations form salts with aqueous formaldehyde, and although Staudinger et al.21 have shown that there is no definite composition to these materials, they are probably co-ordination complexes of the metals with water, hydroxide ions, and a variety of chain lengths of partially polymerized formaldehyde.

The polyvalent cations, which are Lewis acids, also co-ordinate with the carbonyl oxygen atom of nonhydrated formaldehyde, rendering the carbon atom much more subject to nucleophilic attack. It can further be expected that the polyvalent cations would also stabilize the enolate anions of the hydroxy aldehydes and ketones

In this work, it has been shown that a dilute (10-2 molar) solution of formaldehyde can be condensed to a mixture of sugars in conditions designed to simulate a primordial hydrothermal spring. An alkaline medium is unnecessary for this condensation to take place. The reaction takes place at mildly acid and neutral pH. The basic sites on the crystal lattice of the alumina and aluminosilicates probably serve to remove protons from the formaldehyde and various intermediates absorbed on the mineral surfaces, thereby providing the necessary reactant molecules.

A reasonable rationale for the production of hexoses in 10-2 molar solution of formaldehyde and not in a 0.33 molar solution is that in dilute solution an individual reaction intermediate will be absorbed for a longer time on the mineral surface. Conversely, in a more concentrated solution, the reaction intermediate is more quickly displaced from the mineral surface by the other solute molecules. It can be expected that the longer any given reactant remains on the active surface of the catalyst the greater are its chances of undergoing further reactions to form products of higher molecular weight.

Synthesis of Sugars in Potentially Prebiotic Conditions

The formation of sugars from formaldehyde has been studied extensively1, but the reaction has usually been carried out in conditions too extreme to have existed on the primitive Earth. The claim that relatively pure ribose can be obtained by boiling formaldehyde with a suspension of calcium carbonate2 led us to investigate the catalytic activity of "carbonate-apatite". apatite, a very common phosphate mineral, is inactive; we argued that if carbon dioxide was abundant at any stage in the evolution of the ocean, carbonate incorporation into apatite must have been extensive.

A slurry of "carbonate-apatite" prepared freshly by the method of Hayek et al.3, was found to have a pH of 8.5. On boiling with 0.5 molar formaldehyde, it gave yields of up to 40 per cent of sugars. There was an initial induction period of several hours during which no sugars could be detected, then glycolaldehyde, trioses, tetroses, pentoses and hexoses appeared successively. Sugars were separated by chromatography in butanol-acetic acidwater (4:1:5, upper phase) and in acetic acid-pyridinewater (7:3:2) and estimated using the acid aniline Pentoses are present in maximal phthalate spray¹. amount after about 12 h and hexoses after about 24 h. When boiling was continued for longer periods the solution darkened and the sugars gradually disappeared; the hexoses persisted longest. We obtained similar results when we used calcium carbonate as a catalyst, but the whole sequence of reactions proceeded more slowly.

When this experiment was repeated using more dilute formaldehyde, we could still detect sugars from 0-01 melar solution but not from 0.001 molar. The minimum detectable yield in the latter experiment was 1-2 per cent. In these experiments, we used formaldehyde labelled with carbon-14 to obtain greater sensitivity in our analyses. The experiment was discontinued after 14 days. These results are similar to those reported by Gabel and Ponnamperuma4, who used a suspension of Al₂O₃ as catalyst.

We do not believe that the formose reaction as we and others have carried it out is a plausible model for the prebiotic accumulation of sugars. First, it requires concentrated formaldehyde solutions and, second, the sugars formed are decomposed quite quickly. If formaldehyde is the prebiotic precursor of ribose, some method of stabilizing the sugars is essential. The formation of ribosides of the natural bases-for example, adenine-is one possibility, but attempts to bring about this condensation have not been successful. Instead, rather unstable adducts were formed.

The formation of sugars in plausible conditions and their incorporation into nucleosides have not been achieved. Until the problem is solved or by-passed it remains a weakness in theories of abiotic nucleic-acid synthesis.

Study of Microbial Evolution through Loss of Biosynthetic Functions: Establishment of "Defective" Mutants

On appropriate media, mutants which have lost a biosynthetic function may exhibit a selective advantage over parental strains. Is this how "parasitism" became established?

THE availability of complex media (such as higher organisms as hosts) was followed by the appearance of fastidious micro-organisms, defective in one or more biosynthetic functions. Lwoff¹, in his study of the establishment of parasitism, anticipated that, on adequate media, auxotrophic mutants could have a selective advantage over prototrophic parents because of energetic economy (fewer biosynthetic steps). Such an explanation would necessitate the assumption that the prototroph would continue to manufacture the particular metabolite, although it could simply take it from the medium as the auxotroph does. Since Lwoff's work1, feedback inhibition and gene repression mechanisms have been demonstrated which tend to suppress the biosynthetic steps of the prototroph if the end-product is available in the medium. it appeared debatable whether or not a prototroph is at a selective disadvantage compared with an auxotroph.

Here we present evidence which shows that, on adequate media, "defective" mutants, auxotrophs and others, indeed have a distinct selective advantage over the parental strain. The mechanisms of feedback inhibition and/or gene repression which would help the parental strain to economize are not universal and/or not complete enough to offset the advantage that the "defective" strain has in not being involved at all in this particular biosynthetic process. The results also indicate that the more biosynthetic steps dispensed with by the auxotroph (early block; final metabolite available) the more advantage it has. Furthermore, a de-repressed strain, producing more of the final metabolite, is also at a selective disadvantage with respect to the normal repressed one. The work has also been extended to the case in which the actual block is unknown (mutation to azide resistance).

The organism we used was Bacillus subtilis strain 168, its mutants and back-mutants. The purpose of using a back-mutant rather than some wild strain from the "collection" was to ascertain that the two strains studied differ by a single mutational step in the structural gene studied; this is, obviously, of primary importance. To study the selective advantage of one strain over another, the two were grown together in liquid minimal medium with appropriate supplements, and the population changes observed; it has been shown that the comparison of growth rates of the two strains cultivated separately may

*US Public Health postdoctoral fellow. Present address: Microbial Process Laboratory, Chas. Pfizer and Company Inc. Groton. Connecticut.

not lead to a reliable estimate of their selective values.

For a more precise determination of the selective behaviour, the strains were grown in a medium of constant

composition (continuous culture), in an improved version (unpublished work of Eichhorn, H. H., and Morimoto, H.) of the chemostat of Novick and Szilard⁴. At zero time, a sample (1 ml.) of a chemostat culture of one strain was added to a 20 ml. culture of the other strain in a second chemostat. In cases where approximately equal starting numbers of cells of both strains were desired, the contents of both chemostat tubes were mixed and 20 ml. introduced into a third chemostat. The chemostats were set at generation time 4 h (37°C; glucose limiting: 0.55 mmolar). At 24 h intervals (six generations) aliquots of 1 ml. were removed, diluted, spread on appropriate agar media and the proportions of the cells of each strain were determined

(Figs. 1 to 5).

Fig. 1 refers not to auxotrophs but to an azide-resistant mutant. When the spontaneous mutant 168/azi (resistant to 2 mmolar sodium azide on Penassay agar plates) was grown in the chemostat together with its azide-sensitive parent 168 in the absence of azide, it had a strong selective disadvantage: the proportion of 168/azi decreased 100fold in eighteen generations (Fig. 1). The decrease is at first exponential; the curves subsequently flatten out because of the appearance of additional 168/azi cells as a result of spontaneous mutations. The curves for two different ratios of 168/azi to 168 at zero time are parallel; this means that the azide-sensitive strain 168 has an intrinsic selective advantage and does not produce any inhibitor specific against 168/azi. Such inhibitors have been reported^{5,6} but seem to be rare cases. Another example of selection against a "drug" (mutagen)-resistant mutant has been reported recently. Such results may explain why a high proportion of azide-resistant mutants (and probably "drug" resistant mutants in general) does not usually occur in wild populations.

The nature of the genetic injury resulting in azide resistance is not known. More information is available in the case of auxotrophs. When the histidine requiring (his-) mutant 21, obtained by heat^{8,9}, was grown together with its histidine non-requiring spontaneous back-mutant (his+), in the presence of 0.32 mmolar L-histidine, it had a strong selective advantage over his+; the proportion of the latter decreased 4,000-fold in forty-eight generations (Fig. 2). Again, the curves are essentially parallel regard-

less of the initial ratio of the two strains, indicating that the auxotroph his- has an intrinsic selective advantage over its prototrophic parent his+ and is not producing some inhibitor specific (or more active) against his+. The concept that the selective advantage of auxotrophs over prototrophs is not the result of some specific inhibitors is also supported by the generality of the phenomenon.

An indole requiring auxotroph (ind-) in the presence of 0.25 mmolar L-tryptophan exhibits a strong selective advantage over its indole non-requiring back-mutant ind+ (Fig. 3, curves t): the proportion of the latter decreased more than 10^s-fold in fifty-four generations. The viability of chemostat cultures of ind- and ind+ strains before mixing was estimated by comparing the viable count on Penassay plates with the total count in a Petroff-Hauser counter. The average values were 97 per cent for ind- and 100 per cent for ind+. Thus the selective advantage of ind- was not due to its lower mortality.

The site of genetic injury in the his- mutant 21 is unknown; but the mutation in (ind-) is known to result in the absence of indole glycerol phosphate synthetase. In both cases, when the final metabolite (histidine or tryptophan) is present, the block may represent an omission of one or more synthetic steps that follow the blocked one; thus the auxotrophs have a definite selective advantage over the prototroph. Ind- strain, on tryptophan, did not have to (and could not) perform any steps towards the biosynthesis of tryptophan. It seemed of interest to study whether the advantage of this auxotroph over the prototroph is less pronounced when the two are grown on indole instead of tryptophan—that is, when the auxotroph still has to perform one step: conversion of indole to tryptophan. Curve i on Fig. 3 shows the result; the advantage of the auxotroph over the prototroph is not as pronounced as when the two strains are grown on tryptophan (curves t on Fig. 3).

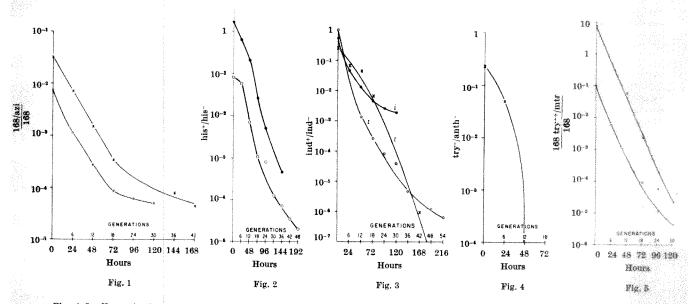

We then investigated whether an earlier block in the same pathway, such as the inability to synthesize anthranilate, has a selective advantage over a late block: in the presence of tryptophan the mutant blocked earlier should manufacture fewer intermediates than the mutant blocked further in the pathway. Moreover, if the point mutation in an early block were polar it would decrease the amount of enzymes made by the following cistrons

and should increase the selective advantage of the mutant-Anthranilate-requiring (anth-) strain SB194 (obtained from Dr E. Nester) was grown together with tryptophan-requiring (try-) strain T3 lacking tryptophan synthetase B (obtained from Dr C. Anagnastopoulos), in the presence of 0.25 mmolar L-tryptophan (Fig. 4). As expected, the anth- strain exhibited a strong selective advantage over try-: the latter disappeared in less than 48 h (twelve generations). In this case, the better growth of the anth-strain could be observed even before mixing, when the two strains were grown separately for 3 days in their chemostats: the try- mutant reached a cell density of

 4.2×10^7 /ml., whereas anth- reached 5.7×10^7 / ml. This predictable behaviour may serve as a tool in cases where one wants to predict which of the several existing pathways or bypasses is most economical and

will be used preferentially by the cell. The genes involved in the biosynthesis of tryptophan in E. coli are known to form an operon, with the operator situated in the anthranilate region 19,11; tryptophan itself (and its analogues such as 5-methyltryptophan) inhibits the synthesis of tryptophan, presumably by contributing to the repression of the operon. In B. subtilis the situation may be similar; the locus influenced by 5-methyltryptophan is also situated in the general location of the anthranilate region 12,13. These results indicate, however, that in the wild strain the repression of tryptophan synthesis by tryptophan may not be complete: some tryptophan synthetase is being made and some tryptophan synthesis may still go on, in contrast to the auxotroph in which this synthesis is completely blocked; the auxotroph can thus be at an advantage. For other pathways which are not controlled at all by a repressible operator, an auxotroph may have even more pronounced advantages. A similar situation may exist for those pathways which are controlled by feedback inhibition which in vivo is not complete.

It seemed of interest to study whether a "de-repressed" mutant is at selective disadvantage with respect to its wild parent. Presumably, in such mutants, the operator is not influenced by tryptophan and its analogues; such strains often contain high levels of tryptophan synthetase^{12,12} and excrete tryptophan¹³. One such "derepressed", spontaneous mutant, resistant to 5-methyl-

Figs. 1-5. Change in the ratio of cell numbers of *B. subtilis* strains indicated on the ordinate on growing them together in a chemestat in minimal broth for the number of hours or generations indicated on the abscissa. The two curves on Figs. 1, 2 and 5, and t on Fig. 3, refer to two different starting ratios. See text for strain designation. Total viable counts: Fig. 1, 2·3 to 2·6 × 10* fml.; Fig. 2, 8 × 10* to 4 × 10* fml.; Fig. 3, 6 × 10* to 1·1 × 10* fml.; Fig. 5, 5 to 6 × 10* fml. Mean viability over 90 per cent. Media supplements: Figs. 1 and 5, unsupplemented; Fig. 2, excess of L-histidine (0·32 mmolar); Fig. 3, excess of L-tryptophan (curves t) or of indole (curve t) (0·25 mmolar); Fig. 4, excess of L-tryptophan (0·25 mmolar).

tryptophan and excreting tryptophan (168 try++/mtr), was grown together with its wild parent 168 in unsupplemented basal medium. It can be seen (Fig. 5) that this "de-repressed" mutant is indeed at a distinct selective disadvantage: its proportion decreased 105-fold in twenty-six generations. Again, this result is independent of the initial proportion of the two strains, indicating an intrinsic selective disadvantage of the "de-repressed" strain rather than the action of a specific inhibitor manufactured by the wild parent. It seems most probable that the disadvantage of the "de-repressed" strain is its useless (uncontrolled) production of large amounts of tryptophan; it is likely that this is why a high proportion of "derepressed" mutants does not occur in wild populations.

These examples help to predict evolutionary trends by means of studies of competitive behaviour. Such studies can probably be extended to include substances other than simple metabolites. For example, the foregoing cases of gene inactivation (his-, ind-, try-, anth-) were results of point mutations. In such cases the economy is in the metabolite only: the structural gene, the messenger RNA, and in many cases (CRM+) the inactive enzyme itself, still have to be manufactured. If, however, such mutants were deletions resulting in the elimination of a DNA segment, and the shortening of the chromosome¹⁴, the additional advantages may include faster replication of the chromosome and saving on sugars, bases, aminoacids and ATP otherwise necessary to synthesize this portion of DNA, messenger RNA and protein. If this is true, a mutant with a deletion would be at a distinct selective advantage over a point mutant and would

supersede the latter. For example, study of tryptophan requiring wild strains of Streptococcus faecalis (ATCC 8042, 8043 and 9790) reveals that in these species the strains occurring in nature have lost one or more of their structural genes (for tryptophan biosynthesis) by deletions and not by point mutations (unpublished results of Zamenhof, S., and Heldenmuth, L. H.). Such mechanisms then could account for the complete disappearance of certain genes during the process of evolution.

Erythrocyte Substitute for Perfusion of Brain

by HENRY A. SLOVITER TOSHIHARU KAMIMOTO*

Harrison Department of Surgical Research and Department of Neurosurgery, School of Medicine, University of Pennsylvania

In a simulated blood plasma 'FX-80', a liquid fluorocarbon with a high solubility for oxygen, maintains the electrical activity of a preparation of isolated rat brain. This is as effective as a suspension of erythrocytes in the same simulated blood plasma.

A SUBSTITUTE for whole blood must be able to transport oxygen, carbon dioxide and glucose (or other metabolic substrate). Its composition must permit exchange of water and ions with extracellular fluid while it maintains the steady state composition of the tissues it perfuses. The many substitutes for blood plasma which have been widely used are able to perform all these functions except the adequate transport of oxygen and carbon dioxide. There has hitherto been no useful substitute for the function of the haemoglobin of the erythrocyte. Haemoglobin is not unique in its ability to carry oxygen. Certain complexes of cobaltous salts are able to reversibly bind oxygen without being oxidized1,2, but attempts to make use of these substances as functional substitutes for haemoglobin have not been successful. The relatively high solubility of oxygen and carbon dioxide in some nonpolar liquids offers the possibility of transporting these gases in the physically dissolved, chemically unbound form. Such a simple mode of transport of oxygen may be better than transport as bound molecules, especially at low oxygen tensions.

* Present address: First Surgical Division, Gifu University School of Medicine, Gifu City, Japan.

A liquid fluorocarbon designated as 'FX-80' (manufactured by the 3M Company, St Paul, Minnesota) has a high solubility for oxygen and carbon dioxide. 'FX-80' is composed predominantly of perfluorobutyltetrahydro-furan and its isomers. When saturated with oxygen, it contains 0.63 ml. of the dissolved gas/ml. (personal communication from J. W. Sargent). This capacity is greater than that of human erythrocytes which when fully saturated contain about 0.46 ml. of oxygen/ml. of cells3. The diffusion of oxygen through the fluorocarbon is quite rapid and it has been possible for mice to survive complete immersion for hours in 'FX-80' into which oxygen is bubbled4.

Gollan and Clark⁵ reported that isolated rat hearts continued to contract vigorously when perfused alternately with oxygenated FX-80° and with oxygenated diluted blood. Presumably, the perfusion with 'FX-80' alone could not be continuous because of its inability to transport substrate to the perfused tissue or to maintain ionic equilibrium. Water and polar substances such as glucose and salts are virtually insoluble in 'FX-80', and so this fluorocarbon cannot carry out the functions of whole blood in the perfusion of an organ, but it should be

able to carry out the functions of the erythrocytes in transporting oxygen and carbon dioxide on the basis of the high solubilities of these gases in the fluorocarbon.

The problem then is to convert the liquid fluorocarbon into particles which are approximately the size of erythrocytes and which are stable when suspended in blood plasma or a fluid resembling it. We have accomplished this by ultrasonic treatment of a mixture of FX-80' and a simulated blood plasma.

We have evaluated the ability of such a dispersion of 'FX-80' to transport oxygen and carbon dioxide and perform other functions of blood by using it to perfuse

an isolated rat brain preparation⁶.

The simulated blood plasma used was an 8 per cent solution of bovine serum albumin in Krebs-Ringer bicarbonate buffer solution prepared as previously described. To a 10 ml. portion of the simulated plasma in a Rosett cooling cell immersed in an ice bath was added 2 ml. of 'FX-80' and this mixture was insonated at 110 W power output for 20 sec with a Branson model W-185C cell disruptor fitted with a 0.5 in. tip. The dispersion so obtained has the appearance of homogenized milk. Microscopic examination of the dispersion showed that the 'FX-80' was dispersed quite uniformly into particles which were about 2-3µ in diameter. The dispersion was quite stable and showed only slight sedimentation after standing several hours. The dispersed material could be sedimented by centrifuging and the sedimented material was easily resuspended without further insonation. A sample of the dispersed material was washed with water by successive centrifugation to remove all soluble protein. The washed sedimented material was analysed by the Lowry method (Folin-Ciocalteau reagent) and found to contain about 5 per cent protein.

Insonation of 'FX-80' in water or buffer solution not

containing protein did not yield a stable dispersion.

The preparation and behaviour of our isolated perfused rat brain preparation have been described. The "blood" which has been used for perfusing this isolated brain is a suspension of washed dog erythrocytes in the same bovine albumin solution which was used to prepare the 'FX-80' dispersion. We have measured the electrical activity and some metabolic functions of the isolated brain when perfused with the 'FX-80' dispersion and compared the results with those obtained in identical experiments except that the "blood" was used for perfusion. In all experiments, closed circuit perfusion was performed at 25° C using 5 per cent carbon dioxide-95 per cent oxygen

and an initial glucose concentration in the perfusion fluid of 200 mg/100 ml. The perfusion fluid was always freshly prepared just before each experiment. In the perfusion fluid the volume of erythrocytes or of the dispersed 'FX-80' was approximately 20 per cent of the total volume. Bipolar electroencephalograms (EEG) were recorded from each side of the brain from four electrodes placed in direct contact with the bone in the frontal ann parietal regions on both sides. Samples of perfusiod fluid collected at intervals during the perfusion were analysed for glucose by a glucose oxidase method using the commercial reagent 'Glucostat' (Worthington Biochemical Co.); lactate was determined enzymatically with lactic dehydrogenase7. In some experiments, measurements of the pH, oxygen tension and carbon dioxide tension of perfusion fluid were made on samples drawn into capillary tubes from the arterial side (from the perfusion line just before the entrance to the brain) and from the venous side (from the superior sagittal sinus through a small hole in the bone and dura).

Table 1. DURATION OF MAINTENANCE OF EEG ACTIVITY OF AN ISOLATED, PERFUSED RAT BRAIN PREPARATION

Perfusion fluid	No, of experiments	Amplitude > 5 μ V (min)	Amplitude $<5 \mu V$ (min)
"Blood" ' FX -80' dispersion Simulated plasma	$^{10}_{10}_{3}$	46-180 (average 115) 44-245 (average 131) 0-4 (average 1)	10-135 (average 62) 23-181 (average 69) 0-2 (average 1)

We have shown that the spontaneous electrical activity of our perfused brain preparation is a very sensitive criterion of its functional and metabolic condition; cessation of perfusion for only 30 sec causes almost complete loss of electrical activity. In the present series of experiments, we have found that when the isolated brain was perfused with the bovine albumin solution alone, the spontaneous EEG never persisted more than 5 min When the perfusion was performed with either "blood" (washed dog erythrocytes in the same bovine albumin solution) or the 'FX-80' dispersion (also in the same albumin solution), the spontaneous EEG usually persisted for more than 2 h. In Fig. 1 are shown portions of the EEG recordings obtained in a representative experiment in which the 'FX-80' dispersion was used and similar recordings from an experiment using "blood". Table 1 lists the results of the series of perfusion experiments which provide a comparison of the ability of ${}^{\circ}FX$ -80' dispersion and artificial blood to maintain the EEG of the isolated rat brain. The duration of the EEG has been

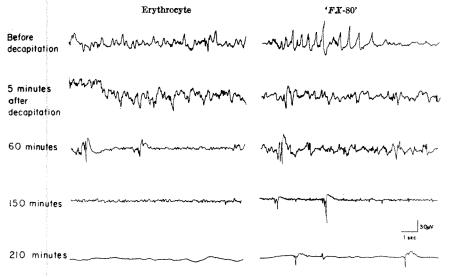

Fig. 1. The spontaneous EEG activity of an isolated rat brain preparation perfused with "blood" (recordings on the left) and another perfused with 'FX-80' dispersion (recordings on the right) at various times.

divided into a period when the amplitude of the activity is more than 5 μV and another when it is less. This was done because it is sometimes difficult to determine the exact time at which activity has ceased completely. Sometimes, after activity has been absent for a time, spontaneous seizure activity appears. It is therefore thought that a comparison of the periods of maintenance of activity greater than 5 µV is a more reliable one. The course of the changes in amplitude and frequency of the EEG with perfusion time was very similar for both the "blood" and 'FX-80' experiments. These results show that there is little difference between "blood" and 'FX-80' dispersion in ability to maintain the electrical activity of the brain and suggest that the dispersed 'FX-80' is adequately performing the gas transport functions which the erythrocyte ordinarily does.

Table 2. GLUCOSE CONSUMPTION AND LACTATE PRODUCTION OF ISOLATED RAT BRAIN PREPARATIONS PERFUSED WITH "BLOOD" OR 'FX-80' DISPERSION

Perfusion fluid	No. of ex- periments	Glucose consumption (mg/h)	Lactate production $(\mu \text{moles/h})$
"Blood" "FX-80" dispersion	5	4·0-6·8 (average 5·3)	12–30 (average 20)
	5	5·1-7·6 (average 6·7)	21–33 (average 26)

The changes with time in the glucose and lactate concentrations of the perfusion fluid for representative experiments with "blood" and 'FX-80' dispersion are shown in Fig. 2. The curves for glucose concentration are almost the same for both types of perfusion fluid. The lactate concentration curves are similar except that the lactate values are initially somewhat higher for the perfused "blood" samples and remain so. Even after exhaustive washing of erythrocytes some lactate is always present and the erythrocytes are producing small amounts of lactate continuously. From the analytical data, we have calculated the glucose consumption and the lactate production during the first hour of perfusion and these values are listed in Table 2. The differences between the values for the two perfusion fluids are not large but the values for the 'FX-80' experiments are significantly larger, both glucose consumption and lactate production being about 30 per cent greater.

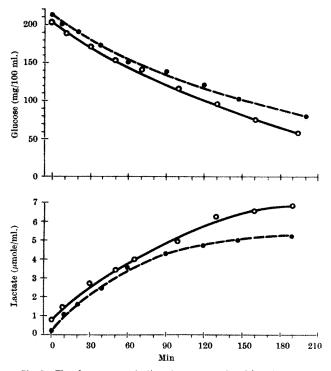

Fig. 2. The glucose concentrations (upper curves) and lactate concentrations (lower curves) of isolated rat brain preparations perfused with "blood" ($\bigcirc-\bigcirc$) or with 'FX-80' dispersion ($lue{lue{lue{---}}}$).

The differences in pH between the "arterial" perfusion fluid and the "venous" fluid were nearly all between 0.05 and 0.12 U ("arterial" always greater) and these differences showed no significant relation to perfusion time. The absolute values and the differences were very similar for the "blood" perfusion and 'FX-80' perfusion experiments.

The oxygen tension of the "arterial" fluid was between 400 and 500 mm of mercury in all experiments at all perfusion times. In the experiments with "blood", the difference in oxygen tension between the "arterial" and "venous" fluid was about 300 mm during the first hour of perfusion and decreased to 150-200 mm after 2 h of perfusion. In the experiments with 'FX-80' dispersion, these differences in oxygen tension were 200-250 mm during the first hour and they dropped to less than 100 mm after 2 h of perfusion. The smaller arteriovenous differences for 'FX-80' dispersion might be expected on the basis of the greater total amount of oxygen carried by 'FX-80' than by erythrocytes. These measurements were not of high precision, chiefly because of some difficulty in obtaining the samples of "venous" fluid. The results, however, demonstrate that there is a significant arteriovenous difference and that its order of magnitude is about the same with both "blood" and 'FX-80' dispersion. When substrate is absent from the perfusion fluid, the electrical activity of the perfused brain persists for only a relatively short time. In two experiments with 'FX-80' dispersion to which glucose was not added, the EEG disappeared in 20-30 min and the arteriovenous difference in oxygen tension dropped to almost zero in less than 1 h. This suggests that the arteriovenous differences we observed are indicative of maintenance of the metabolic and functional activity of the brain.

The values for CO₂ tension in the "arterial" fluid of all samples were in the range 32-40 mm and the "venous" samples were greater by 9-15 mm during the first hour. This difference decreased to 2-7 mm at the end of the second hour. There was practically no difference in these values whether "blood" or 'FX-80' dispersion was used as perfusion fluid.

Our results demonstrate that 'FX-80' in dispersed form is adequately carrying out the essential functions of the erythrocyte. The significant buffering capacity of the erythrocyte is, of course, lacking in 'FX-80'. The brain is such a sensitive organ with respect to oxygen supply that it is likely that 'FX-80' dispersions can be used with equal success for perfusion of other organs. Such dispersions may have considerable advantages over blood in organ perfusion experiments and for use in vitro. because haemolysis cannot occur and there is no haemoglobin or other pigment to interfere with spectrophotometric or other measurements. Furthermore, the ' $\dot{F}X$ -80' could be used in conditions of temperature and pH and in the presence of toxic agents which the erythrocyte cannot withstand.

We have done preliminary experiments on the intravenous infusion of 'FX-80' dispersions in intact animals. The animals have died and death seems to be caused by some unknown effect on the lungs.

This work was supported by a research grant from the US National Institutes of Health. We than!: Mr J. W. Sargent for the 'FX-80', Mrs Lynn Kaliner for technical assistance and Mr M. Petkovic for analysing the dispersed FX-80.

ASTRONOMY

Continuum Radiation from Quasi-stellar Sources

It is known that the mechanism of synchrotron radiation from relativistic electrons in a magnetic field provides a valid explanation of the continuum electromagnetic radiation from extended cosmic sources, such as radio galaxies. This explanation, however, in respect of the nuclei of quasi-stellar sources meets serious difficulties. Assuming the quasi-stellar sources are at cosmological distances it is found that their internal radiation field is so intense that it causes overwhelming loss of fast electrons by inverse Compton scattering. Alternatively, a strong magnetic field reduces the lifetime of the fast electrons unacceptably.

I shall show that these difficulties are simply overcome if it is assumed that relativistic protons are responsible for the bulk of the synchrotron radiation, particularly at its maximum in the millimetre and infrared wavelengths, just beyond the limit usually set by self absorption.

For simplicity, I assume the relativistic protons to be mono-energetic with energy $W = \gamma m_0 c^2$, where m_0 is the rest mass and $\gamma \gg 1$, although no great difficulty arises in assuming a more plausible power-law energy spectrum.

Consider the frequency, v_* , below which self absorption occurs, which marks approximately the peak intensity of the radiation spectrum. Here the Rayleigh–Jeans surface intensity, v_*^2 $3W/c^2$, just matches the radiation emitted by all protons throughout the volume of the source. Thus

$$3\nu_{\bullet}^2\gamma m_0c^2/c^2 \simeq \frac{4\pi}{3} R^3n \ (4\pi R^2)^{-1} \frac{2e^4B^2\gamma^2}{3m_0^2c^3\nu_{\bullet}}$$
 (1)

where n is the particle density of protons per unit volume, R is the radius of the source, B is the magnetic field strength and e the proton charge. Here, a simple approximate formula for the synchrotron radiation emitted by one proton per unit frequency at v_* has been used.

Equating the radiated power to the flux received at distance D from the source gives

$$S_{r_*} = \frac{R^2}{D^2} \frac{3v_*^2 \gamma m_0 c^2}{c^2} \tag{2}$$

According to the theory of synchrotron radiation, the radiation from ultra-relativistic particles peaks at γ^2 times the gyro frequency of the rest mass, thus

$$v_* \simeq \gamma^2 eB/2\pi m_0 c \tag{3}$$

Eliminating \(\gamma \) from equations (2) and (3) yields

$$V_{\star}^{-5/2} S_{v_{\star}} \simeq \left(\frac{R}{D}\right)^2 m_0 (2\pi m_0 c/eB)^{1/2}$$
 (4)

To obtain another relation between R and B, assume equipartition between magnetic field energy and particle energy density, which is the most economical assumption possible, thus

$$nW = B^2/8\pi \tag{5}$$

From equations (1) and (5)

$$cv_*^3/R = \frac{4\pi^3}{27} \left(\frac{eB}{2\pi m_0 c}\right)^4$$
 (6)

is obtained.

From equations (4) and (6) R and B can be estimated independently, knowing y, S_{n} and D_{n} .

independently, knowing v_{\bullet} , $S_{r_{\bullet}}$ and D.

Take as an example the quasi-stellar source nucleus 3C 273B, which is assumed to be at a cosmological distance of 470 Mparsec. From observational data² take $S_{r_{\bullet}} = 2 \times 10^{-21}$ ergs cm⁻² c/s⁻¹ at $v_{\bullet} = 10^{12}$ c/s as approximately the self absorption limit. For these values equations (4) and (6) give $R = 2 \times 10^{15}$ cm and $B = 1.7 \times 10^{4}$ gauss. Then it follows that $n = 10^{7}$ cm⁻³ and $\gamma = 200$. In this field, the proton life time for radiating is about 1 yr. The total magnetic energy equals (by hypothesis) the total relativistic proton energy and is about 0.5×10^{54} ergs, which totals also about the rest energy of one solar mass. Curiously the values of B and γ are not so much greater than those which occur in solar flares².

In this model, based on proton radiation, I conclude that the quasi-stellar source nucleus is a small object with R about 1 light day, well within the limits imposed by observed short period fluctuations of intensity. The magnetic field is strong, yet the total magnetic energy is still very small in comparison with a radio galaxy.

Case of the Vanished Correlation in Statistics of Quasi-stellar Objects

Longair and Scheuer recently reported the results of their exhaustive studies concerning the possible correlation between optical and radio intensities and the redshifts in a large sample of quasi-stellar objects. Plotting the observed visual optical magnitudes m, and the radio fluxes S_{178} and S_{1400} against the red shifts z, they found significant statistical correlations between these quan-The next step was to eliminate the effects of relativistic time dilation comprising: the fact that the radiation received was emitted with higher frequency; the diminished energy of each photon; the contraction of the observed frequency band relative to the band in which the radiation was emitted. All these effects of time dilation remain the same whether or not the redshift is considered to be the result of the expansion of the universe. After constructing the graphs of the corrected values m_b' , S_{178}' and S_{1400} the authors make the following statement: "The most striking result is that the correlation . has disappeared completely'

This disappearance, similar to that of the Cheshire cat, which left nothing but the grin, can easily be explained on the basis of the point of view which I recently proposed concerning the nature of the quasi-stellar objects. I indicated that the free path of a light ray propagating through the space of the universe populated by galaxies is comparable with the distance we can penetrate into space, using modern instrumentation. Thus if we assume that the original sources of white light are located at very large distances (thus corresponding to the very early evolutionary stages of the universe), their light must almost inevitably pass through at least one of the galaxies on its way to us. This will result in absorption lines similar to those caused by the interstellar gas in our Milky Way, so that the observed Doppler effect in the absorption lines will correspond not to the recession velocity of the source but rather to the recession velocity

of the intervening galaxy. It should be mentioned that, because of the continuous dispersion of the galaxies in the universe, a passage of that light ray through a galaxy is more likely to take place during the earlier stages of its journey rather than during the later ones. No correlation is to be expected between the intensity of light or radiowaves and the redshift of the absorption lines observed in quasi-stellar objects. This is exactly the conclusion at which Longair and Scheuer have arrived.

Evidence of Continuum Emission from Jupiter at 18 Mc/s

In 1966 it was reported by Dulk and Clark¹ that almost continuous, bursty, radiation from Jupiter can be detected at low frequencies if an aerial receiver system of sufficient sensitivity is available. Relative to this, Stone, Alexander and Erickson² found a marked increase in emission probability at 26·3 Mc/s using the large array at Clark Lake Radio Observatory. Prolonged periods of activity were observed by Warwick³ on a number of occasions in 1960. Evidence is presented here of a related effect at 18 Mc/s observed on several occasions during the 1966–67 apparition of Jupiter.

The term "continuous" as used by Dulk and Clark¹ refers to prolonged periods of bursty radiation of the type already familiar to observers of Jupiter. The "continuum" radiation reported here is a relatively steady emission sometimes appearing as a background to the more usual bursty type of emission. According to Dulk (private

communication) true continuum was hardly ever observed during the course of his observations.

Our observations were made with an interferometer consisting of two identical broadside arrays, each of four whole wave dipoles, on an east-west baseline of sixteen wavelengths. The beam of each array was centred on the zenith and had half-power points at about ±13° in the north-south direction and about ±25° in the east-west direction. During the period of the observations, Jupiter was about 8° to the south of the zenith at the upper culmination and no other point sources of comparable intensity were within the response pattern of the aerials. The receiver was phase-switched with a variable timeconstant of either 0.1 or 1.0 sec and a bandwidth of 3.5 kc/s. This could, if necessary, be swept electronically over a frequency range of ± 0.1 Mc/s every 2 min; thus Jupiter could be distinguished from certain types of interference or from a distant station. Two different pen-recorders had to be used during the apparition. These had time-constants of about 0.25 sec and 0.5 sec as seen in Figs. 1 and 2, respectively. The overall response of the system was therefore effectively variable from about 0.25 to 1.0 sec. The event characteristics are given in Table 1. The corresponding periods of activity can be divided into two classes. In class 1, it can be seen that the conventional Jupiter bursts, for example, on November 7, December 9 and 10. 1966, seem to be superimposed on a fringe envelope and that the pen does not return to the zero-centred baseline either between each burst or throughout an entire fringea period of about 15 min. On December 16 and 17, 1966, and January 18, 1967, for example, in class 2, it can be seen that the pen returns to the baseline during a fringe as might be expected if the radiation consisted solely of sporadic outbursts. Both types of occurrence can be seen in different sections of the records, December 17, 1966, and February 12, 1967. In the record for December 10, 1966, the effect of shortening the receiver time-constant to 0.1 sec is shown. It can be seen that this did not alter the form of the fringes, and it did not cause the pen to

^{*} Changed to 0-1 from 0907 to 0948.

return to zero between the bursts of activity although the system noise increased somewhat.

It is suggested that on some occasions continuum emission must have been present in the Jupiter radiation to cause the class 1 type of activity. Absolute calibration is not available for these records, although the general adjustment procedure of the instrument implies that the intensity of the continuum radiation would be less than 10^{-21} W.m⁻²(c/s)⁻¹. A total of seventeen events out of the forty-three observed during the period November 5, 1966, to March 4, 1967, contained evidence of continuum emission, if this is arbitrarily defined as any event containing one complete fringe during which the pen did not return to the baseline. That this effect was not observed on every occasion presumably indicates that the continuum emission is either not a frequent occurrence at 18 Mc/s or, perhaps, that it is always present but usually of too low an

intensity to be recorded by the interferometer. Each array of the interferometer has been enlarged to ten whole-wave dipoles and made electronically steerable in the north-south direction for further observations during the next apparition.

The research was supported by the US National Aeronautics and Space Administration.

PLANETARY SCIENCE

Early History of the North Atlantic Ocean and its Margins

THE formation of the Atlantic Ocean in late geological history was conceived (as a scientific hypothesis) in the second half of the nineteenth century when sufficient became known of the stratigraphical framework of Earth history. Suess (1885-1904) surveyed the striking similarities which suggested continuity of structure and stratigraphy of the opposing margins of the Atlantic and Arctic oceans, and he postulated that foundering of part of a once more extensive Laurasian continent gave rise to the Atlantic Ocean. Against geophysical evidence this view survived until recently (for example, Beloussov). On the other hand. from speculation about the reasons for the distribution and shape of the continents and oceans, and especially about the origin and influence of the Moon, an Atlantic fission of Laurasia was successively postulated, notably by Owen in 1857, Snider in 1859, Fisher in 1881 and 1889 (possibly the first to suggest Atlantic separation by convection), Pickering in 1907, Taylor in 1910 (who first detailed a scheme for the opening of the Arctic and separation of Greenland from both Europe and America involving strike-slip between Greenland and Ellesmere Island) and Baker in 1911. Wegener (1912-1928), in spite of resort to a feeble mechanism for drift, by bringing palaeoclimatic and other evidence to bear, succeeded in gaining widespread attention and support. It needed only the addition of palaeomagnetic evidence to finally convince most scientists. Continental drift was so challenging a concept that most attention had been absorbed in the questions of its general validity and mechanism. Its exploitation to explain earlier events in Earth history was left to those who related the long history of orogenic activity to substantial continental movement. Alternatively, it has been suggested that continental drift may have been a process characteristic of the last 5 per cent of Earth history. But most "pre-drift" reconstructions even recently have been static in not being related stratigraphically.

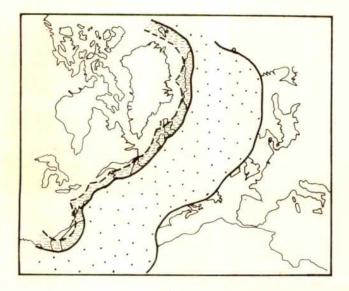

A recent application of the drift concept to earlier history has been made by J. T. Wilson. His question "Did the Atlantic close and then reopen?" assumed drift as a

phenomenon of general application and supplemented a specific hypothesis to test it (Fig. 1). Some aspects of this are examined here. The principal novel feature of Wilson's hypothesis does not seem to be supported by the evidence he gave, but it may well anticipate appropriate new data to support some part of it.

The part of Wilson's hypothesis which is not novel concerns the history of what is termed here the North Atlantic geosyncline (defining geosyncline by thickness of sediments and not by the depth of water in which they formed). For example, in 1928 W. van der Gracht² suggested (page 72) "It would seem as if in the older Paleozoic, before the Caledonian diastrophism, America might have moved westward faster than Eurasia, opening a Paleozoic Atlantic geosyncline, which was partly closed again during the Caledonian diastrophism. . . . In the Mesozoic period, and increasingly in the Tertiary revolutions, the drift of the American continent . . . tearing open the old rift and causing the present Atlantic." Van der Gracht's comprehensive hypothesis was well based on what was then known of the tectonic history of the Atlantic borderlands, but his thermal mechanism (adapted from that of Joly3) was shortly to be improved on by Holmes 4.5, who also used the concept of a Caledonian orogenic concentration of sial to generate a zone of upward and outward convection and so split it open along its length. For Wegener the Mid-Atlantic ridge had been the linear scar of continental fission analogous to the African rift valleys and Red Sea, but perhaps Molengraaf⁶ first saw its significance as a volcanic zone of extension, which refuted the westerly continental drift of Joly and van der Gracht and supported a

symmetrical spreading of the Atlantic.

It had long been known that the Atlantic orogenic structures arose from a complex of geosynclines, including Dana's type (Appalachian) "geosynclinal". Bailey and Holtedahl' considered the nature of the seas which covered the developing geosynclines and preceded the orogenic belt before closing and reopening. Caledonian geosynclines were then conceived essentially as thicknesses of early Palaeozoic rock*. It has now become clear, as the history of the crystalline parts of the orogens has been unravelled, that similar or much greater thicknesses of late Pre-Cambrian rocks are also involved in the Appalachians*-11, Scotland*12, Norway*13, East Greenland*14 and Spitsbergen*15. Thus similar conditions, probably marine, persisted in

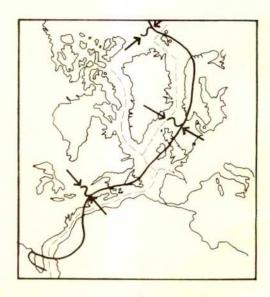

Fig. 1. Closing of proto-Atlantic Ocean in Palaeozoic time according to Wilson'. (a) Early Palaeozoic; coarse stipple is proto-Atlantic Ocean; dashed shading is island are geosyncline. (b) Mid- to late-Palaeozoic; the thick line marks the closure of the proto-Atlantic and the chief compressed geosyncline lies to the west of this; the dashed line marks the approximate line of later Atlantic opening.

these areas, possibly for some hundreds of millions of years before the Lower Palaeozoic orogeny¹⁶.

It may be still a matter for debate whether orogeny in general, or the Caledonian diastrophism in particular, involved significant and substantial compression with closing of the geosynclinal areas. This has long been assumed in general by most of those who advocated drift (for example, Argand, Termier, du Toit) and it has been argued (for example, recently; see refs. 17-19) that if convection caused continents to drift, the same kind of movements have also compressed zones of lithosphere. In one of the first hypotheses giving a detailed sequence of continental movements through Phanerozoic time in the North Atlantic-Arctic region 20, I made such an assumption and later illustrated it by a sequence of palaeogeological maps²¹ (Fig. 2). The first of these shows an area of Pre-Cambrian and Lower Palaeozoic sedimentation but gives no indication of the depth of water (which may well have varied considerably in place and time). There is, however, some evidence of shallow water facies and occasionally of desiccation and there is no reason to suppose that any of the facies are abyssal. The aqueous environment is usually assumed to have been marine, judging from the Palaeozoic faunas, Pre-Cambrian glauconite, occasional halite pseudomorphs and possibly from the widespread dolomites and stromatolitic limestones. But Wilson¹ supplements this idea by inserting his wide and deep proto-Atlantic ocean to the east of the geosyncline which he depicts as a relatively narrow system of island arcs (drawn as one involving little orogenic compression).

The closure of this area (marine geosynclinal + ocean basin) was then suggested by Wilson to have been gradually accomplished through Upper Ordovician to Carboni ferous time (Fig. 1b). The closure had been analysed into component movements allowing a distinction to be made between the northern and southern parts of the North Atlantic region^{20,21} (Fig. 2a-d). Phases of disturbance. reflected in discordances and facies in the Carboniferous record, are evident throughout the region, but evidence of substantial late Palaeozoic compression is limited to the Armorican-Appalachian belt (Suess' Altaids), whereas increasingly northwards Permian conditions seem to have been progressively more quiescent. On the other hand, Mid-Palaeozoic (Caledonian, Taconian and Acadian) structures were formed with considerable intensity along the whole site of the subsequent North Atlantic fission.

The explanation of the contrasting history of northern and southern parts of this region may be found in the existence of a mobile (palaeo-) Tethys. Three relatively stable blocks (North America and Greenland, Spitsbergen and Northern Europe and Africa) moved somewhat independently. In mid-Palaeozoic time the whole North Atlantic geosyncline, from Alabama to Spitsbergen, was compressed—not necessarily simultaneously in all areas

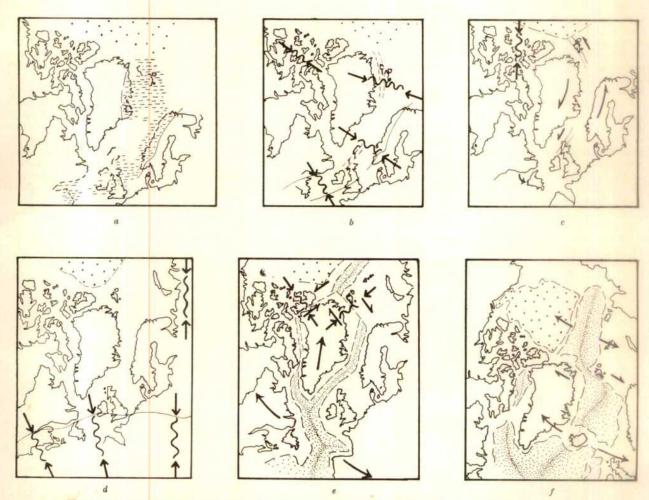

Fig. 2. Sequence of movements in North Atlantic-Arctic region during Phanerozoic time, schematized from Harland^{28,31}. (a) Early Palacozoic; the shading shows the extent of the North Atlantic geosyncline in Palacozoic time (other Palacozoic geosynclines are not shown). (b) Silurian; directions of "Caledonian" compression are shown diagrammatically by arrows and folded lines. (c) Late Devonian showing the new positions after sinistral strike-slip movements along the Atlantic orogen. (d) Late Palacozoic; directions of "Hercynian-Appalachian" compression. (e) Early Tertiary Atlantic fission and northward movement of Greenland is shown by finely stippled new ocean and compression to the north-east and north-west of Greenland. (f) Recent; spreading of new Atlantic and Arctic Ocean basins continues and the maps also show the continuing ancient Arctic basin by coarse stipple.

(Fig. 2b). This closed and to a large extent eliminated the seas between Europe and America. In late Palaeozoic time Africa moved differentially with respect to the newly welded Laurasia with a net movement towards Greenland and along a direction parallel to its axis (Fig. 2d). Seen from North Europe the closing direction was thus turned between early Silurian and late Carboniferous time through a large angle (60°-90°) and initiated both the graben faulting characteristic of Old Red Sandstone times and the postulated sinistral late mid-Palaeozoic strike-slip faulting of Scotland^{22,23} and Spitsbergen²⁰. My own reconstruction of this phase^{20,21} fits, but does not depend on, the report of analogous movements described by Wilson²⁴ as the Cabot Fault, which has been seriously questioned²⁵ (Fig. 2c). A prediction of this hypothesis, however, is that sinistral strike-slip faulting can be expected to extend somewhere in the Appalachian region or towards north-west Africa. Such a fundamental fault system might well provide a suitable zone for later fission 20.

The subsequent opening of the Atlantic has similarly been analysed into distinct elements. An independent northward movement of Greenland against Spitsbergen and Ellesmere Island resulted first in compression and then, respectively, in dextral and sinistral strike-slip which accompanied the opening of the North Atlantic and Arctic ocean basins^{20,21,26,27}. In so far as Africa moved independently with respect to Meso-Europe, this led to differential opening of the northern and southern parts of the Atlantic basins. The final stage in this oceanic evolution is the familiar situation accommodating the mid-oceanic rifts and ridges6,28-30. My account of later continental movements has been greatly simplified, partly by omitting the qualification, in each case, that continents might be associated with equally stable oceanic extensions; for it is assumed that the differential movements in the crust and upper mantle depend on activity in the deeper mantle.

The distinctive feature of Wilson's hypothesis1 is the postulate of a proto-Atlantic ocean basin in Lower Palaeozoic time alongside the North Atlantic geosyncline. Wilson showed the chief part of the geosyncline as a thin zone bounding eastern Laurentia. It was separated from Nordaustlandet in Spitsbergen, Fennoscandia, southern British Isles, eastern Newfoundland and maritime provinces, and some of North West Africa, by the postulated ocean basin of width similar to that of the present Atlantic, and with parallel sinuous sides. This is a daring reconstruction.

The almost exact parallelism of the two margins of the supposed proto-Atlantic as drawn by Wilson (analogous to those of the present Atlantic) suggests that it was formed by fission (? along a still earlier orogen) as van der Gracht suggested2. This may not have been intended, but if the reconstruction is true it suggests a prior question: Did an eo-Atlantic geosyncline close (? Grenville) before the proto-Atlantic opened again to close (Caledonian) before re-opening as the Atlantic? Alternatively, the evidence of late Pre-Cambrian diastrophism (for example, Grenville, Carolinidian) can be explained as an earlier stage in the closing of a North Atlantic geosyncline that was initiated still earlier.

Much of the evidence on which Wilson based his separation of the two sides of a proto-Atlantic depends on a familiar recourse to faunal provinces. But these are probably too uncertain to be used as a basis for such a construction. I have been thanked in general for private information on Spitsbergen¹ and I must disclaim communicating any evidence from Spitsbergen which would support such a separation of Nordaustlandet and Vestspitsbergen as Wilson proposes.

The Hecla Hoek (part of the North Atlantic geosyncline) is not (as Wilson attributes to me) a Lower Palaeozoic eugeosyncline. The chief volcanic record of the geosyncline (comprising about 12 km in Ny Friesland) terminates about 7 km beneath the Lower Cambrian and Ordovician carbonate strata, so that in latest Pre-Cambrian and Lower Palaeozoic time conditions were relatively stable, only exposing sediments occasionally above sea level as evidenced by desiccation cracks. Whereas previously²¹, I had supported Orvin32 and Sandford33 in regarding Nordaustlandet as the margin of the geosyncline, questioned it in 196034 and our current view16, pending publication of a Norsk Polarinstitutt investigation of Nordaustlandet, is to regard the succession on both sides of Hinlopenstretet as broadly similar. Even if the earlier view is correct it relates only to the earlier part of the Pre-Cambrian succession. Indeed, it is perhaps easier to correlate Pre-Cambrian Hecla Hoek rocks in detail across the strait than across any other unexposed area. Wilson's hypothesis of a proto-Atlantic ocean basin as it concerns Spitsbergen in early Palaeozoic time seems to be as surely wrong as anything in nature can be.

There may, however, be some truth in Wilson's hypothetical proto-Atlantic. It is unlikely that there would be very thick sediments throughout the North Atlantic geosynclinal region (Fig. 2a). Geosynclines and ocean basins may have been interspersed and evidence for these may be sought in the sedimentary record. But abyssal facies are difficult to identify after metamorphism. In particular, it is not known on what kind of basement the geosyncline rested in most places. In Spitsbergen no certain evidence of a pre-Hecla Hoek basement has yet been published. Late Pre-Cambrian thermal events³⁵ are difficult to interpret but could relate either to a metamorphic episode within some geanticlines or to a marginal (?) Carolinidian diastrophism brought into proximity with Ny Friesland by sinistral strike-slip faulting in late Caledonian time¹⁶. The early, largely basic, eugeosynclinal phase could have initiated geosynclines on a marginal ocean floor. If so it was a late Pre-Cambrian ocean, possibly even pre-Grenville. But we do not yet know whether it existed, nor do we know on which margins of such a hypothetical ocean the geosynclines could have developed. The possibility of such a proto-Atlantic ocean may be tested by investigating the distribution of eugeosynclinal facies (or otherwise) at the base of late Pre-Cambrian geosynclinal successions throughout the North Atlantic. The (proto) Arctic basin shown in Fig. 2a-f could well be an extension of such a proto-Atlantic ocean and the geosynclinal area in Fig. 2a would need supplementing and widening by a trough or by basins of non-geosynclinal ocean floor.

Variations in Two New Zealand Glaciers during the Past 800 Years

A METHOD for dating surfaces which uses measurements of the maximum diameters of the lichen thalli which encrust

rocks has been developed and fully described1.

We have used this procedure, with some slight modifications, to study the moraines of the Mueller and Tasman glaciers in the Mount Cook region, Canterbury, New Zealand. The termini of these glaciers are at the same altitude (about 2,500 ft.) and are only 4 miles apart so that conditions for lichen growth are similar at both places. Two deviations were made from Beschel's method: first, in the case of oval thalli the longest axis rather than the shortest was measured; second, defined sampling areas were not used because of the irregularity of the terrain. The results obtained allowed us to construct comparable chronologies for advances of the two glaciers covering a period of about 400 yr. On older surfaces at the Tasman glacier the record extends back a further 400 yr.

A glacial advance is defined for our purposes as an increase in ice volume substantial enough to form distinct, ridged lateral moraines and terminal push moraines. Complex series of these moraine ridges are present near the glaciers at Mount Cook, the oldest existing laterals and latero-terminals being most distant from the present position of the ice. The morphology, relative spatial positions, relative heights and vegetation cover of the ridges demonstrate their chronological position relative to one another and show that parts of them have been free from ice since they were formed. It is on these surfaces that lichen measurements were made. In many cases only short fragments remain of what were obviously once extensive moraine loops. Subsequent destruction of much of the length of these moraines has been chiefly through the agency of vigorous melt-water streams or by overriding by later ice advances. In some instances, there is evidence for forward movement of the glacier snouts during glacial advances, but in other cases there is no such evidence, either because the terminal moraines proper have been destroyed by subsequent events or because forward movement did not occur. Changes in height of the glacier surfaces are clearly recorded by the series of lateral and latero-terminal ridges.

We identified surfaces of known ages at the Mueller glacier, formed about AD 1930, 1913 and 1890, from historic records^{2,3} and a surface formed between AD 1730 and 1750 from the study of Lawrence and Lawrence* in which tree growth rings were used. Calibration growth curves for two species of lichen present on these surfaces, Rhizocarpon tinei (Tornab.) Run. and R. candidum Dodge (both identified by Mr D. Galloway, Department of Biochemistry,

University of Otago), are given in Fig. 1.

The age of only one surface—AD 1890—is known from historic records at the Tasman, but a curve drawn through the plot of maximum diameter of R. tinei on this surface, against surface age, closely agrees with that from the Mueller. Similarly, a curve for R. candidum plotted from a surface dated at about AD 1740 (by means of the R. tinei

curve) parallels the curve obtained for this species at the Mueller. The ages of undated surfaces at both the glaciers were extrapolated from these growth curves. shows the ages of distinct advance moraine ridges as determined from the largest lichen diameters, taking the dates at their face value to the nearest 5 yr back to AD 1600, and to the nearest 10 yr from AD 1600 back to AD 1150. In some cases, ranges of dates are given which, back to AD 1580, represent approximate time ranges from beginning to end of the glacial advances. On older moraines these ranges simply represent the scatter of dates. Because the age estimates are likely to be minimal, the oldest date on each surface may be taken as the nearest approximation to true age on surfaces older than about 400 yr.

The estimates of the dates of glacial advances determined in this way match those for historically recorded advances of glaciers in the European Alps and glaciers in the Caucasus Mountains from the late sixteenth century onwards, and seem to show that most of these glacial events were synchronous in the northern and southern hemispheres. Matthes noted that the Grindelwald glaciers advanced in 1595-1620, 1719, 1743, 1770-79, 1814-22, 1838-50, the Vernagtferner in 1599-1601, 1678-81, 1771, 1820, 1848 and advances of the glaciers of the European Alps occurred generally in the 1850s, 1875-1890s, 1910-13. 1916-20 and 1926. In the Caucasus, advances occurred in 1850-60, 1877-87, 1907-14, 1927-33.

As far as we are aware, the Mount Cook moraines seem to provide a more complete record of glacier variations

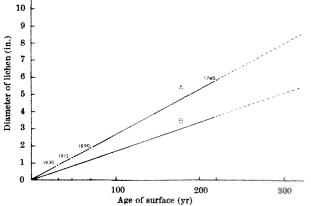

Fig. 1. Growth curves for Rhizocarpon tinei (A) and R. candidum (B) on surfaces of known age at the Mueller glacier.

during the past millenium than any which have so far been studied elsewhere in the world. The relative heights and positions of latero-terminal moraines indicate that the advances were of varying magnitude. In particular, the advances in the seventeenth and eighteenth centuries were massive and both Mueller and Tasman glaciers apparently pushed out beyond older terminal moraines at those times, but did not destroy parts of the earlier lateral moraines. On some occasions, however, the two glaciers behaved differently. The advance of the Mueller in the mid-eighteenth century was greater than most earlier and all later advances, but the advance of the Tasman in 1890 overrode most of the length of the mid-eighteenth century moraine and was the greatest advance since the thirteenth century. Ice levels remained high at the Mueller and Tasman glaciers between 1890 and about 1916, but so far there is no evidence for distinct advances during this period. Since about 1916 some hundreds of vertical feet of ice have been lost from the surface of both glaciers by down-wasting, but there has been little terminal retreat.

The Beschel method¹ has recently been criticized by Jochimsen⁶ on theoretical grounds related to the physiology and ecology of lichen and as a result of his observations in Austria. In our opinion this criticism does not apply to our results for the following reasons: (a) it is possible to draw a straight line through measurements of the greatest diameter of two lichen species on surfaces of known age; and (b) comparable results were obtained for two lichen species on the moraines of two glaciers.

THE increasing use of conodonts in studies of Palaeozoic stratigraphy in Europe and North America has recently received added impetus by the discovery of faunas in other continents where broadly similar faunas have been described from strata of similar ages. So far, however, there has been only one published record of conodonts from the Indian subcontinent¹. A well preserved fauna of some 1,200 individual conodonts has recently been extracted from a sample of siliceous limestone, collected from a locality near Lutherwan, Kashmir (33° 6′ 90″ N., 75° 35′ The insoluble residue also yielded many fragments of bony material and numerous fish teeth. The strata yielding conodonts lie just below the Muth Quartzite which has been assigned a Middle Devonian age on the basis of fossils collected from a locality 1 mile north of Naubug (33° 44′ 30″ N., 75° 23′ 30″ E.), Anantnag Distt, Kashmir.

The area was first mapped by Middlemiss², who assigned

Ranges from Bischoff and Zieglers. Full line shows common occurrence; broken line indicates rare occurrence. For further details, see Zieglers.

an Upper Silurian age to the beds, and Gupta³ later remapped the area and named the strata the Naubug Beds. The beds consist of blue grey to rusty calcareous sandy shales and siliceous limestones, and have yielded a large fauna consisting of brachiopods, trilobites, corals, crinoids, cystoids and nautiloids. This has been described by Gupta³, who interprets it as of Upper Silurian-Lower Devonian age.

The Naubug Beds are succeeded, apparently conformably, by the Muth Quartzite. Devonian osteolepid and dipterid fish remains have been collected from dark calcareous shales situated at the base of the Muth Quartzite south-west of the Margan Pass⁴, and these suggest a Lower or Middle Devonian age for the base of the Muth Quartzite.

Gupta³ has collected a rich fauna of brachiopods, corals (including Calceola sandalina), trilobites, pelecypods and gastropods from the middle portion of the Muth Quartzites, and these suggest a Middle Devonian age for the fossil-

iferous portion of the quartzites.

The conodont fauna is dominated by polygnathid specimens, although other individuals are also abundant. The following species are present: Polygnathus cristata Hinde; P. ordinata Bryant; P. pennata Hinde; P. webbi Stauffer; P. linguiformis Hinde; P. rugosa Huddle; Polygnathus cf. P. dengleri Bischoff and Ziegler; Polygnathus cf. P. varca Stauffer; Ancyrodella rugosa Branson and Mehl; A. rotundiloba (Bryant); Bryantolus cf. B. paeckelmanni Bischoff and Ziegler; Icriodus spp.; Lonchodina sp.; Trichonodella sp.; Bryantodus spp.; Ozarkodina spp.; Hindeodella sp.; Panderodus sp.; Ligonodina sp.
All these individuals are in a comparable state of

preservation, most being fragmentary, although detailed preservation of the fragments is good. The specimens of Panderodus are lighter in colour and may be reworked. Numbers of polygnathid specimens show morphological trends in which they approach palmatolepids and ancyrodellids. There are two specimens in which individual conodonts are used together by material that resembles

"bony material" in colour and texture.

Table 1 shows the ranges of these various species, as recorded by Bischoff and Ziegler⁵ for Germany. This fauna clearly lies near the Middle-Upper Devonian boundary, and it probably falls within the dubia rotundiloba-Subzone, as originally defined. The precise zonal position in Germany is still not fully established, however, although Ziegler has erected a new hermanni-cristata-Zone between the varca and the asymmetrica-Subzones. He regards this latter subzone as lowest Upper Devonian, but there is a gap between the vertical ranges of the two diagnostic cephalopod genera, Maenioceras and Pharciceras.

The importance of the present fauna lies partly in the fact that the nearest known faunas of comparable age are those of Europe, the Spanish Sahara7 and Australia6, and partly in the remarkable overall similarity of the faunal assemblage to those of other areas. The correlation which we propose on the basis of conodonts agrees well with that proposed independently on the basis of other in-

vertebrate fossils3.

PHYSICS

Electron-beam Dosimetry using the Radiation-induced Fluorescence of Polyethylene

WE have recently examined various effects of high-speed electron radiation on the properties of polyethylene. Among other effects, we observed that the intensity of fluorescence (excited by mercury-lamp illumination of a polyethylene sample previously electron-beam irradiated) increased linearly with radiation dosage in the range from 0 to 40 Mrads. The fluorescence is persistent, reproducible and easily measured, and thus may be useful for dosimetry applications.

Irradiation of polyethylene has been studied from many viewpoints, but relatively little dosimetry work has Charlesby¹ has suggested that polyethylene might be used as a dosimeter by using infrared spectroscopy to follow changes in unsaturation caused by irradia-The fluorescence, thermoluminescence and phosphorescence of polyethylene have all been investigated**.

but not from the dosimetry standpoint.

In our experiments, a variety of polyethylene samples with density and molecular weight variations of different form (that is, bulk or sheet), and with and without antioxidant, were examined. For standardization purposes TR 201 'Marlex' in 1/16 inch sheets was selected for our studies. Irradiation was carried out with a High Voltage Engineering 1.0 MeV Insulating Core Transformer Electron Accelerator. Dosages ranged from 0 to 160 Mrads, in 10 Mrad steps. All irradiations were performed in air at room temperature, at 10-0 Mrads per pass

The fluorescence spectra were obtained with a Cary 15 spectrophotometer and 1512 fluorescence attachment. A Hanovia 735 A 0070 source was used in conjunction with a filter of aqueous $NiSO_4.6H_2O$ (500 g/l.) and a Corning 5840 glass filter. The path length of the nickel sulphate solution was 1 cm; the principal excitation wavelengths were in the areas of 3120 Å and 3330 Å, with lesser amounts at 3650 Å and 2537 Å. The wavelength of the polyethylene fluorescence emission spectrum selected for measurements was 4470 Å; the spectrum appeared as a broad band from 6000 Å to about 3600 Å (Fig. 1).

The results of our measurements are shown in Figs. 2 and 3, and may be summarized as follows. Fluorescence intensity at the 4470 Å wavelength varied linearly with

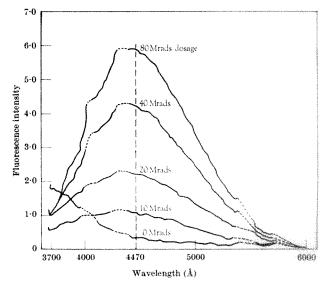

Fig. 1. Fluorescence spectra of TR 201 'Marlex' 1/16 in, polyethyiene sheet irradiated with different dosages. The scattered mercury lines of the exciting illumination are indicated as breaks in the fluorescence spectra.

dosage up to 40 Mrads and then fell off. Anti-oxidants did not affect linearity but seemed to have some effect on intensity. The anti-oxidant itself showed no fluorescence before or after irradiation. The fluorescence persists for periods at least as long as three years after irradiation. The effect of heat is to quench the fluorescence.

It seems from the results that the polyethylene fluorescence may in fact be useful as a dosimetry system for electron-beam irradiation in the appropriate dosage

We have not, at this point, made an extensive investigation of the fluorescence mechanism. It has, however, been shown by various authors5-7 that several forms of unsaturation are present in irradiated polyethylene. It is

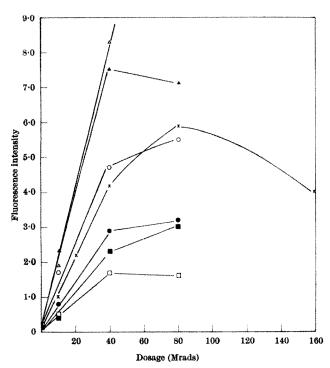

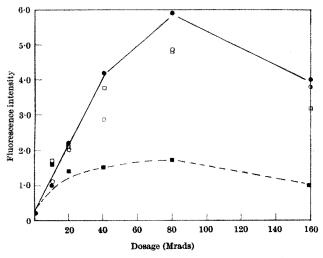

Fig. 2. A plot of fluorescence intensity against dosage for a variety of polyethylene samples. \triangle , Allied 1220 (bulk), high molecular weight, no anti-oxidant; \triangle , Allied 1230 (bulk), high molecular weight, with anti-oxidant; \bigcirc , 'Marlex' TR 201 (sheet), irradiated in 1966; \times , 'Marlex' TR 201 (sheet), irradiated in 1964; \rightarrow 'Marlex' TR 201 (bulk), with anti-oxidant; \rightarrow 'Marlex' 704 (bulk), no anti-oxidant; \rightarrow 'Marlex' 604 (bulk), with anti-oxidant.

Effect of heat on fluorescence intensity of irradiated TR 201 1/16 in specis. • Room temperature 25°C continuous; 'Marlex' 1/16 in. sheets. ● Room temperature 25° C continuous; O, heated at 50° C for 2 h; □, heated at 100° C for 2 h; ■, heated at 150° C for 2 h.

possible that the carbonyl group, which absorbs ultraviolet radiation in the 2700 Å-3400 Å region, is involved, because our principal excitation wavelengths range from 3120 Å-3330 Å. We are proceeding with our investigation of this aspect.

Stability of Dilute Viscoelastic Flows

STEMMING from Toms'1 original observation, several investigators² have observed the phenomenon that dilute concentrations of linear polymers of high molecular weight in water and other solvents will act to reduce greatly the hydraulic friction. Although the viscosity in solution of the effective polymers is higher than that of the base liquid, it has been shown that the frictional resistance is reduced even when the data are correlated on a solvent-based Reynolds number³.

This phenomenon is usually attributed to a modification of the turbulent flow structure4, and a pronounced thickening of the laminar sublayer of the turbulent flow has been observed from measurements of velocity profiles. Although the use of pitot tubes for velocity profile measurements may be subject to normal stress errors, the causal relationship between sublayer and thickening and friction reduction seems to be proved. Such a conclusion suggests that the polymers act to stabilize the flow in the buffer region. Furthermore, if stabilization is enhanced in the presence of turbulence, it would be expected that the polymers would also delay the point of instability and In earlier, unreported extend the transition regime. experiments by one of us (W. B. G.), this delay of transition was observed. It was subsequently found that the flow remained laminar even in the presence of severe roughness elements7.

In the literature, two types of pipe friction factor data are found. In one case, the flow goes into normal transition⁸, following the Newtonian turbulent flow characteristic with a subsequent and increasing reduction of friction at higher Reynolds number (or higher strain rates). By using higher polymeric concentrations or more effective polymers, there are instead one or two breaks in the friction factor characteristic which indicate increasing flow resistance with respect to laminar Newtonian flow. Ram and Tamir¹⁰ assume that the first break indicates transition into turbulence and identify this region as structured turbulence. It is also possible to assume that the higher strain rates have induced a change in rheological fluid properties rather than a change in flow state, such as suggested by Peterlin¹¹ for a very high molecular weight polymer in a very viscous solvent. The purpose of this study was to clarify this point by measuring the friction factor characteristics in association with observations of flow stability.

Various concentrations (0, 0.5, 1, 2, 5, 10, 30, 300 p.p.m.) of polyethylene oxide ('Polyox' coagulant, Union Carbide

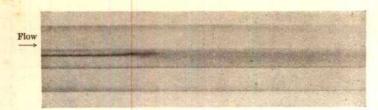

Fig. 1. Dye burst in water. $R_d = 2,280$, and tube diameter = 0.058 in.

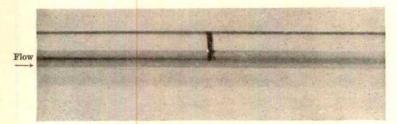

Fig. 2. Dye burst in aqueous solution of 0.5 p.p.m. of polyethylene oxide. $R_d = 4,440$, and tube diameter = 0.058 in

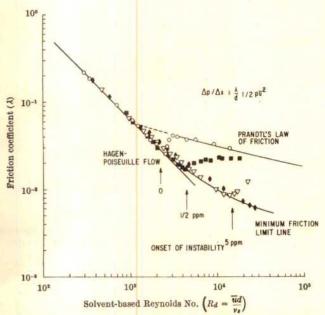

Fig. 3. Flow resistance of aqueous solutions of polyethylene oxide in a 0-055 in. diameter capillary. O. Tap water; .05 p.p.m. 'Polyox' coagulant; .05 p.p.m. 'Polyox' coagulant; .05 p.p.m. 'Polyox' coagulant.

Co.) were tested in capillary tubes of 0.055 and 0.101 in. diameter. Several static pressure taps were used to avoid entry length effects. Flow stability was observed by means of a dye filament in a 0.058 in. diameter glass tube with a 6 to 1 inlet contraction nozzle; and also by observation of the stability of the exit jet¹² of both the glass and metal capillary tubes.

Flow instability is characterized by turbulent diffusion of the dye filament, as shown with water in Fig. 1, and also erratic behaviour of the exit jet as each turbulent burst develops and passes through the tube. The onset of instability with water occurred at a diametral Reynolds number of

$$R_d = \frac{\bar{u}d}{v} = 2,240$$

approximately 6 in. downstream of the inlet. The same behaviour was found to occur with 0.5 p.p.m. of 'Polyox' coagulant in water, except that instability was delayed until $R_d = 4,400$ and occurred farther downstream at about 24 in. from the inlet. Close inspection revealed that transition was composed of turbulent bursts separated by

laminar regimes, just as is observed with Newtonian flows¹³. Figs, 1 and 2 show the ends of these turbulent bursts, at camera positions of 10 and 34 in., respectively.

With higher polymer concentrations, the stability increased monotonically. A critical Reynolds number of 14,840 was obtained at a concentration of 5 p.p.m., and at 30 p.p.m. the flow remained stable up to the limits of the test facility $(R_4 = 26,000)$.

These results are shown in Fig. 3, superimposed on the friction factor-Reynolds number data of representative concentrations (0, 0.5, 5, 30 p.p.m.) in the 0.055 in diameter tube, correlated using a solvent-based Reynolds number. The data points are seen to depart from the laminar characteristic much earlier than the loss of flow stability. Thus this fluid system, which is pseudoplastic or shear thinning at sufficiently high concentrations, exhibits shear thickening at high strain rates; and a dominant factor in the ability of linear polymers of high molecular weight to reduce

friction is caused by the enhancement of flow stability, both in delaying transition and in stabilizing the buffer region of turbulent flow.

The envelope of these data prescribes a minimum friction limit line where the friction factor may be described in the form

$$\frac{1}{\lambda} = 8.70 \log (R_d \sqrt{\lambda}) - 16.1$$

or, approximated in the simpler form of

$$\lambda = 1/\sqrt{R_d}$$

Furthermore, it is found that good correlation is obtained from this shear thickening, laminar flow regime by using a solvent based Reynolds number, as shown in Fig. 4. Here data for 30 and 300 p.p.m. of 'Polyox' coagulant in tap water are shown for two tube diameters, 0.055 and 0.101 in.

These observations of the delay in transition taken together with thickened laminar sublayers and suppressed influence of roughness elements suggest that the macromolecules enhance flow stability in a very general manner;

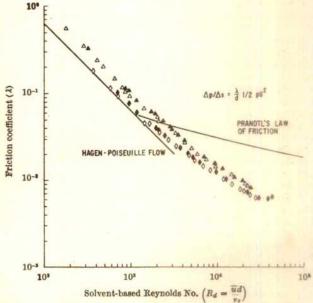

Fig. 4. Flow resistance of aqueous solutions of 'Polyox' coagulant. △, 300 p.p.m., tube diameter of 0.055 in.; ♠, 300 p.p.m., tube diameter of 0.101 in.; ♦, 30 p.p.m., tube diameter of 0.055 in.; ♠, 30 p.p.m., tube diameter of 0.101 in.

not only through a more stable velocity profile, but also through elastic properties in the Orr-Sommerfeld equations.

THE SOLID STATE

Irradiation Creep in Several Metals and Alloys at 100° C

Enhanced stress relaxation under neutron irradiation is well known and has been observed in more than a dozen non-fissile materials^{1,2} (ref. 1 gives a review of earlier work), and recently steady state irradiation creep has been observed in nickel³. This communication briefly describes the results of an experiment designed to compare the irradiation creep of several metals and alloys at about 100° C. So far, no published data have shown the effect of differing metallurgical condition on the irradiation creep behaviour of a given material and the effects of such a variation, in two alloys, were also investigated.

The specimens were made from molybdenum, nickel, titanium, Nimonic alloys PE16 and 80A and an AISI type 316 stainless steel, in the form of helical springs of 0.5 in. diameter and wound from wire of 0.04 in. diameter; each spring had twenty-five active turns. These dimensions are such that a deflexion of 0.05 in. corresponds to a surface shear strain of 10-4. The chemical compositions of the metals and alloys are given in Table 1. Twelve springs were used; they were hung in two strings of six springs each, under tensile load, in a D₂O-flooded thimble in a hollow fuel element in the Dounreay Materials Testing Reactor. The temperature of the springs was determined by y-heating in the various components of the apparatus and boiling of the surrounding D₂O. At each of six successive reactor shutdowns the springs were hoisted into a portable lead cell, which was positioned above the hollow fuel element, and photographed through lead glass windows in the cell walls. Measurements of these photographs, showing reference surfaces above and below each spring and an adjacent scale, permitted the spring extensions to be calculated to ± 0.3 mm. The final calculated neutron dose, achieved after about 2,000 h irradiation, was 3×10^{20} n.v.t. (> 1 MeV) at the centre line of the apparatus. The neutron flux drops by less than 10 per cent over the region occupied by the springs and the centre line dose is used, in Table 2, for every spring.

Examination of plots of extension versus dose showed linear creep for nickel, Nimonic 80A, Nimonic PE16 in the fully heat treated (FHT) condition and titanium. The titanium plots passed through the origin, but the lines for the other three materials made positive intercepts with the strain axes suggesting the existence of a transient in the period between zero dose and the first measurement at 6×10^{19} n.v.t. (> 1 MeV). The stainless steel specimens all showed entirely transient forms; by 6×10^{19} n.v.t. (> 1 MeV) the strain in the annealed specimen had apparently saturated, but the cold-worked (CW) specimens did not saturate until between 12 and 18×10^{19} n.v.t. (> 1 MeV). The Nimonic PE16 specimen in the solution treated $(S\Gamma)$ condition also saturated before the first measurement. Table 2 summarizes the observed transient deflexions, steady state deflexion rates and total creep strains. For control tests, one spring of each material was exposed at 98° C in water, for the same length of time the springs were in-pile and their extension measured with a cathetometer. In no instance was a deflexion exceeding 0.5 mm observed.

In magnitude the pure metals creep the most, the higher stressed nickel spring having extended slightly more than two elastic deflexions. This agrees with more than two elastic deflexions. previous work1, where greater rates of stress relaxation were observed in pure metals compared with alloys. The small creep strain and early saturation observed in the annealed 316 stainless steel also agrees with earlier stress relaxation work on type 18/8 stainless steel¹. Comparison of the cold-worked and annealed stainless steel specimens shows that the former show more irradiation creep although they are stronger in thermal creep at temperatures below which recovery occurs. This inversion is also seen in Nimonic PE16, where the solution treated spring creeps less than the normally stronger, fully heat treated spring. The behaviour of the Nimonic 80A is similar to that observed by Taylor and Jeffs2; a transient followed by steady state creep. The heat treatment given by Taylor and Jeffs to their specimens is different from that used in this experiment and a more quantitative comparison does not seem possible. The stress exponent of creep is evidently close to 1 for nickel (both transient and steady state) and cold-worked stainless steel (transient)

and to 2.6 for titanium (steady state).

Unexpectedly, it was found that the titanium springs twisted, apparently linearly with time, in the horizontal plane. After the final exposure in-pile the lower and higher stressed springs had twisted by about 100° and 130°, respectively, the horizontal angular rotation of the wire ends tending to uncoil the springs. The possibility of ratcheting of the springs on the screwed connectors to The possibility of which they were spot welded when the apparatus was assembled was excluded by comparing the positions of the wire ends on photographs taken after assembly and after the final exposure in-pile. Twisting of helical springs is expected for geometrical reasons4 but is usually very small. Titanium springs when tested in the laboratory twisted slightly $(\sim 10^{\circ})$ when either stressed to give, on loading, the same total deflexion as the irradiated specimens or allowed to creep to the same extent at a higher stress and temperature than experienced by the in-pile springs. Titanium displays irradiation growth when bombarded by fission fragments and might be expected to grow under neutron irradiation also. The wire texture was determined and it was found that there was a pronounced preferred orientation with the basal plane of the h.c.p. cell parallel to the wire axis. To obtain the observed sense of twisting a contraction along the wire would be required which is incompatible with the preferred orientation and the elongation in the [1120] direction observed by Buckley⁶. Hydride platelets may precipitate in the titanium, but would give twisting of opposite sense to that observed if the platelets are deposited on the {10I0} planes which are known to be the primary hydride habit planes6.

Meaningful strains cannot be quoted for the molybdenum springs which were found to be disappearing rapidly presumably by radiolytic oxidation. The wire diameters were measured after the final exposure and were 0.027 in. and 0.026 in. for the higher and lower stressed springs, respectively. From elasticity theory the corresponding deflexions ought to have been 2.1 cm and 2.2 cm, the actual deflexions were 4.2 cm and 4.8 cm. It therefore seems likely that creep has occurred, but because the stresses on the springs have more than doubled it is probable that a large proportion of this would be thermal creep. Rapid corrosion of molybdenum under irradiation has previously been reported.

Formation of Zinc Ferrite at Low Temperatures

It has been considered that phase changes such as that of cubic (or tetragonal) to trigonal iron (III) oxide¹ (often called γ and α ferric oxides, respectively) involve diffusionless, topotactic or epitactic processes^{2,3}. The evidence for this view has been derived from observations on selected single crystals-namely, the comparatively large ones suitable for study by X ray diffraction, or the very small ones satisfactory for electron diffraction. Recent work on powders of calcium sulphate4, cubic iron (III) oxide8 and aluminium oxide, however, indicates that phase changes in these materials do not take place until the temperature is high enough for a considerable degree of mobility to exist in the system. In each case the transformations were associated with marked reductions in surface area, visible sintering and improvements in the crystallinity of the systems. These phenomena indicate a substantial degree of movement as would be the case if the materials crystallized by the diffusion-fed growth of nuclei. Nevertheless, the transformations in question occur well below the Tammann temperatures, being first detected at about a third of the melting point expressed in degrees absolutethat is at temperatures where surface diffusion alone might be expected to be in operation?.

It was thought that striking evidence as to the extent of mobility in iron (III) oxide at temperatures at which the rate of transformation of the cubic to the trigonal form becomes appreciable, could be gained by establishing evidence of reaction with a second compound. Such a reaction could take place only by diffusion, and this communication gives some details of the reaction of iron (III) oxide with zinc oxide at temperatures in the neighbourhood of

400° C.

Reaction between zinc oxide and the trigonal and cubic forms of iron (III) oxide was brought about as follows. Zinc oxide and the appropriate hydrous iron (III) oxide or hydroxide were mixed for 3 h in a mechanical mortar in the correct proportions to give zine territe (zinc iron (III) oxide—spinel type, ZnFe₂O₄). Samples (2 g) of the mixture were then placed in a reaction vessel attached to an all-glass apparatus already described, and heated for 6 h at 270° C in vacuo. Water, which is largely removed by this treatment4,5, is highly active in the system and its effects were minimized and standardized by dehydrating and outgassing under a constant set of conditions. It was shown that no ferrite was formed during this treatment. When the sample had been dehydrated the temperature was raised to a selected value for a further 6 h.

Zinc oxide (composition: zinc oxide, 99.5 per cent; water, 0.39 per cent; organic oxides, 0.13 per cent; sodium. 0.005 per cent; magnesium oxide, 0.0001 per cent) of particle size 0·1-1µ, and a surface area of about 10 m²/g was used. Unless indicated to the contrary, the mixtures were made up from precipitated hydrous iron (III) oxide (composition: ferric oxide, 78-3 per cent; water, 19-9 per cent; ferrous oxide, 0.05 per cent; nitrate, 0.001 per cent; chlorine, 0.010 per cent; ammonia, 0.04 per cent) very similar to that used by Molony and Ridge' when the trigonal iron (III) oxide was required. For the cubic oxide (the material was highly disordered and so was not regarded as tetragonal1) precipitated iron (III) oxide hydroxide crystallographically similar to the mineral lepidocrocite was used. In this case, the material was taken from the same batch used by Ridge, Molony and Boell*. Measurements by nitrogen adsorption gave values of about 150 and 110 $\rm m^2/g$ for the surface areas of the two oxides, respectively.

The products of heating the mixtures of oxides were analysed for zinc ferrite by X-ray diffractometry, the integrated intensities of the diffraction peak for the 2.99 Å spacing being used to determine the amount of ferrite. The values used are the means of two independent

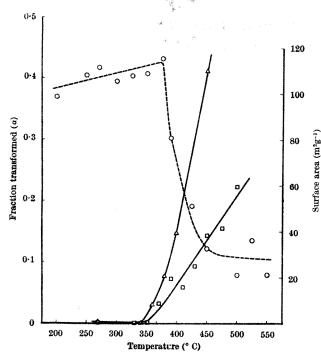

Fig. 1. Fraction (a) of iron (III) oxide combined with zinc oxide in 6 h in vacuo plotted against temperature.

Cubic iron (III) oxide;

C, the surface areas are for cubic iron (III) oxide;

oxide alone as determined by Ridge, Molony and Boeil*.

determinations and I per cent of ferrite could easily be detected in artificial mixtures. It was shown that the small neighbouring diffraction peak in the case of the cubic oxide did not interfere.

Fig. 1 shows temperature plotted against the fraction (a) of the reactants converted into ferrite for systems containing iron (III) oxide in the cubic and trigonal forms. It is seen that reaction can be detected at 360° C and a equals about 0.5 at 450° C for trigonal oxide. The surface areas obtained by Ridge, Molony and Boell⁵ for the cubic oxide are also shown, and it is seen that reaction coincides with the sharp reduction in the surface. These facts indicate that there was sufficient mobility in the cubic oxide studied previously to account for the phase change on the basis of the growth of diffusion-fed nuclei.

The formation of zinc ferrite has been extensively studied using what was probably relatively unreactive iron oxide (say fired at 600° C) or haematite in systems open to the atmosphere 7,10-12. No reaction was detected until the temperature had been raised to about 650° C. We believe that the difference between these findings and those reported earlier results from differences in the conditions of the materials and experiments. The comparatively high surface areas of the oxides allow intimate contact. Furthermore, the high degree of cleanliness of the surfaces could allow higher rates of surface diffusion. A possible example of the effects of surface cleanliness is provided by the fact that a mixture of zinc oxide and powdered haematite gave a yield of about 2 per cent zinc ferrite when heated for six hours at 450° C in vacuo after having been outgassed at 270° for 6 h. When the same mixture was heated at 450° C in a crucible in a furnace or when air was admitted to the reaction vessel after outgassing at 270° C, no reaction took place. Apart from enhanced diffusion over clean surfaces the only other possible explanation for this behaviour is that the higher content of vacancies in materials heated in vacuo increases the rate of body diffusion. This, however, does not seem likely at 450° C, at which temperature the loss of oxygen was less than 0.0007 per cent, as determined by collecting the evolved gases and analysing them.

When a mixture of zinc oxide and the highly reactive iron (III) oxide described here was heated at 450° C in the air, zinc ferrite was formed.

For reaction to occur between the two oxides, they must both be capable of diffusion. The melting point of zinc oxide is 1,800° C indicating a Tammann temperature of about 760° C (400° C for surface diffusion). Bearing in mind the approximate nature of the derivation of these temperatures, the reaction of zinc oxide at about 360° C is probably in accord with the concept of the Tammann temperature and the analogous temperature for surface diffusion. Nevertheless, it seems a little difficult to believe that surface diffusion alone was responsible for the formation of zinc ferrite at 450° C in view of the rapidity of the reaction-namely, a yield of about 50 per cent in a period of 6 h (see Fig. 1).

CHEMISTRY

Nuclear Magnetic Resonance as a Method for Continuously Monitoring Rehydration

Previous work¹ has established nuclear magnetic resonance (NMR) as a method for determining moisture content of foodstuffs. The principles have been further employed² in obtaining rehydration and dehydration curves for batches of samples pretreated for different times. We have extended the use of NMR to include continuous monitoring of rehydration processes.

The uptake of water by several dried materials (for example, macaroni, peas, lentils, collagen fibres) has been followed with an NMR process control instrument (PCI). The experimental method is simple: a known volume of water is added to a weighed dry material in a 100 ml. Nessler tube in the instrument probe. The sample requires no control in packing. The relative rate of uptake of water shown in Fig. 1 is obtained by observing the increase with time in the NMR signal area as recorded directly by the PCI. Calibration of the instrument and a knowledge of the initial water content of the dry sample are required for determination of the absolute water uptake.

The method is based on the fact that pure water has proton magnetic resonance relaxation times of a few seconds3. When water is close to, or bonded with, an immersed solid the relaxation times shorten4. Conditions can be chosen such that in a water-solid mixture the protons of the pure (free) water are RF saturated5 to give a low signal, whereas those of the water associated with the solid are virtually unsaturated and give a much higher signal. If this is achieved, the signal per unit mass from the associated water will be much greater than that from the free water. If we consider the case of rehydration

of a solid sample, the signal will increase as the amount of free water decreases and associated water correspondingly increases. Thus by selecting suitable instrumental conditions, it is theoretically possible to follow rehydration processes. It should be noted that the process control instrument used in this work, manufactured by Newport Instruments, Newport Pagnell, Buckinghamshire, has a gate which defines the width of signal accepted. If the relaxation times shorten greatly, the signal width may exceed the gate width and the peak area observed may decrease. This, however, is not at present relevant.

It is possible to derive an equation predicting the shape of the signal increase curve. Let f_t = fraction of water associated with the solid sample at time t; F = signal/gof the free water; B = signal/g of the water associated with the sample; W = total weight of water present; $S_t =$ observed NMR signal area at time t; and Z = zero point

error of the instrument.

Then, assuming that Z, B, W and F are constant (for any experiment),

$$S_t = (1 - f_t) WF + f_t WB + Z$$

= $f_t W (B + F) + WF + Z$

This equation shows that the time scale of the rehydration of the sample can be represented as in Fig. 1 by the NMR signal curve. By weighing the rehydrated sample and knowing the dry weight and water content of the sample initially, the NMR signal can be related to weight change and Fig. 1 altered to a weight against time curve. The curve obtained for rehydration of macaroni supports these ideas. A weight increase against time curve was obtained independently for the macaroni by weighing samples of wet macaroni after different uptake times. When points on this weight curve are plotted against the NMR signal from the process control instrument, at corresponding times, a straight line results. This suggests that the curves correspond exactly in shape and the

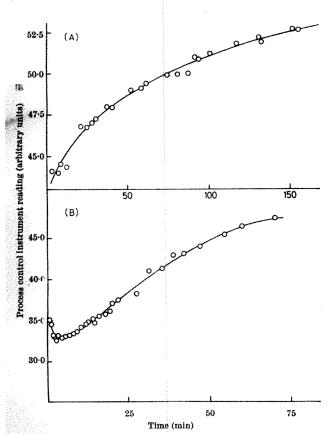

Fig. 1. A, Rehydration curve for macaroni; B, rehydration curve for

method is valid. Both the weighing and NMR rehydration experiments were carried out at 22° C.

Usip only the PCI signal curve and the dimensions of the sample, it is possible to calculate diffusion coefficients for water into dry materials. Ref. 6 gives equations for planar, spherical, cylindrical and tubular samples relating the fractional uptake of water at any time to the sample dimensions and diffusion coefficient. If we assume that the water uptake by macaroni is diffusion controlled and apply the equation in ref. 6 to the PCI curve, we obtain a value at 22° C for the diffusion coefficient of water into macaroni of 1.6 to 2.3 × 10-7 cm² sec-1 (this compares with the value obtained by Fish of 2.4×10^{-3} cm² sec⁻¹ for potato starch gel at 25° C).

The initial dip observed in the rehydration of dried peas in Fig. 1 is interesting. The origin of the peas and the experimental temperature affect the size of the dip, which increases at lower temperatures and disappears at about 25° C, above which temperature it cannot be observed. The dip is thought to be caused by leaching out of pea sugars, for if the peas are repeatedly soaked and washed and then dehydrated, the rehydration curve shows no initial dip. The dip also depends on the RF level used,

and is unobservable at low RF levels.

It may be mentioned that dehydration rates can be similarly observed. Warm air is blown through a moist sample while it is in the instrument probe, and the reduction in NMR signal as water is removed is recorded.

Optical Nitrogen-15 Analysis of Small Nitrogen Samples using a Noble Gas to sustain the Discharge

In view of the dominant part which protein plays in nature, the isotope nitrogen-15 is valuable as a tracer for nitrogen, especially in agriculture, biology and medicine.

Nitrogen-15 is usually analysed by mass spectrometry, but it is now well established 1-4 that the abundance of nitrogen-15 in biological samples can be routinely analysed by optical emission spectroscopy.

The sensitivity of this tracer method is ultimately determined by the smallest amount of excess nitrogen-15 (above natural nitrogen-15) which can be accurately measured, which is at present about 10-100 ng of excess nitrogen-15 by the mass spectrometric methods and by the optical method. This sensitivity is, however, not sufficient in many tracer investigations. For example, an amino-acid spot on a paper chromatogram may contain only 0-1 µg of nitrogen with 0-1 ng of excess nitrogen-15. In this particular case, an increase in sensitivity of measurement of at least a hundred-fold would be necessary.

We have found that a considerable increase in the sensitivity of the optical method can be obtained by using a noble gas as a sustainer in the electrodeless discharge

tube containing the nitrogen sample.

We used pure nitrogen and noble gases from the Linde Company, München, in a standard discharge tube made of rasotherm ('Pyrex') glass by the Karl Kummer Company, Thüringen, a high frequency generator constructed in our laboratory⁷ and a Hilger and Watts quartz spectrograph, model E 742, modified in our laboratory⁸. Our vacuum line was essentially the same as that described elsewhere with the addition of the nitrogen and noble gas containers, and appropriate dosing volumes.

The discharge tube was evacuated by baking and sputtering with krypton or argon before the nitrogen or the mixture of nitrogen and krypton or argon was added. The various pressures, and thereby the mixing ratios, were measured with an 'Autovac' gauge, type 3294 B, from LKB, Stockholm. The tube was air-cooled during

discharge.

Using the standard discharge tube, it has recently been found that 5 µg is the smallest amount of nitrogen that can be analysed by the optical method. This we have found to be reproducible with pure nitrogen. Furthermore, using krypton or argon at a pressure of 1 torr as a sustainer, quantities of natural nitrogen in the range 0.5-5 µg were analysed for nitrogen-15 abundance to an accuracy of ±5 per cent. This constitutes a reduction of the lower limit by an order of magnitude.

Using a quartz capillary, 2 mm bore and 3 in. long, the smallest quantity of nitrogen which could be analysed was reduced to about 0.1 µg. This quantity of nitrogen contained about 0.5 ng of nitrogen-15, which approaches the amount mentioned in the amino-acid example given

A detailed investigation of the use of adding noble gases as sustainers (and possibly, internal standards) in optical nitrogen-15 analysis will be made in the near future.

Chemisorption of Propane on Platinum Surfaces in the Presence of Pre-adsorbed Water

The chemisorption of saturated hydrocarbons on platinum surfaces has been studied by several authors¹⁻³, whose results imply that chemisorption of hydrocarbons is accompanied by extensive dissociation of the molecule, at least at temperatures above 80° C (ref. 3). It is assumed that some C-C and much C-H is dissociated at temperatures of about 100° C.

For catalytic processes in the presence of water, in which the chemisorption of saturated hydrocarbons is

involved, it is interesting to know how the chemisorption is affected by adsorbed water. In order to study this question, we have investigated the chemisorption of propane on platinum in the presence of pre-adsorbed water.

In the experiments, Raney platinum was used as adsorbent. Its surface was cleaned by an oxidationreduction treatment with gaseous oxygen and hydrogen

and aged as described elsewhere2.

The adsorption experiments were carried out with an electro-magnetic vacuum microbalance (Sartorius-Werke, Göttingen); the experimental temperature was 100° C. Water vapour at various pressures was admitted for various periods of time, and the increase in weight caused by water adsorption was recorded. The apparatus was evacuated (10^{-6} mm mercury) in order to remove gaseous and weakly adsorbed water, leaving a certain quantity of water adsorbed on the surface. Subsequent admission of propane (1 mm mercury) led to a further increase in weight, which was reduced on evacuation. The remaining increase in weight of the sample will be referred to here as "net weight increase on chemisorption of propane". Because this net weight increase might include, besides propane chemisorption, a contribution resulting from water desorption, we carried out independent determinations of the amount of propane chemisorbed by oxidizing the chemisorbate by admission of oxygen (1 mm mercury) at 100° C. This led to the complete oxidation of the surface species to give carbon dioxide, which desorbed. Mass spectrometry of the product gas allowed us to determine the carbon content of the chemisorbate, and thus the number of chemisorbed propane molecules.

The experimental results are plotted in Fig. 1 and Fig. 2which show, respectively, the amount of chemisorbed propane and the net weight change on propane chemisorption as a function of the amount of water pre-adsorbed on the catalyst surface. Fig. 2 also includes a plot of the difference of the amount of chemisorbed propane and the net weight change, which represents the amount of water displaced

from the surface on chemisorption of propane.

The results may be summarized as follows. (a) The quantity of chemisorbed propane is independent of the degree to which the surface is covered with pre-adsorbed water, which ranged between 0 and 1.9×10^{15} molecules of water/cm² in this investigation. (b) Compared with the number of platinum surface atoms-

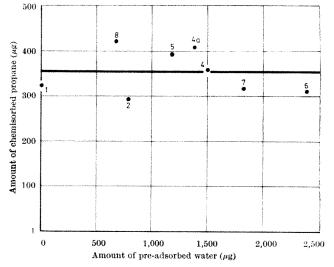

Fig. 1. Amount of chemisorbed propane as a function of coverage of the surface with pre-adsorbed water. The numbers at the dots denote the experiment number; the solid line represents the average value of the experimental data. Temperature, 100° C; weight of catalyst sample, 0.800 g; BET specific surface area of catalyst, $5.2~\mathrm{m}^2/\mathrm{g}.$

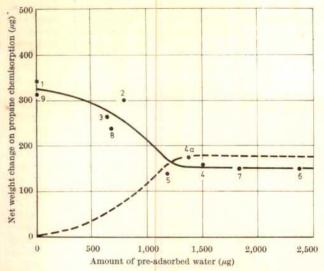

Fig. 2. , Net weight change on propane chemisorption as a function of surface coverage with pre-adsorbed water. The numbers at the dots denote the experiment number. - - - , Amount of pre-adsorbed water displaced on chemisorption of propane (difference between amount of chemisorbed propane—355 µg, solid line of Fig. 1—and net weight change). Temperature, 100° C; weight of catalyst sample, 0.800 g; BET specific surface area, 5.2 m²/g.

cm2, which is the mean of the values for the three most important crystal faces (100), (110) and (111)—the number of chemisorbed propane molecules is small- 1.2×10^{14} /cm². Thus one propane molecule is chemisorbed for every ten platinum surface atoms. (c) At low surface water concentrations, the amount of water displaced from the catalyst surface on chemisorption of propane increases with increasing coverage of the surface with pre-adsorbed water. The displaced quantity is constant above a water coverage of 1·1×1015 water molecules/cm2 or about one water molecule for each platinum surface atom. (d) The maximum amount of water displaced on chemisorption of propane is 205 µg per sample. This corresponds to about 1.6 × 1014 molecules of water/cm2. Compared with the propane value of 1.2×10^{14} , this leads, approximately, to a one-to-one correlation between chemisorbed propane and displaced water molecules.

A qualitative picture of the chemisorption of propane at 100° C in the presence of adsorbed water may be built up from the results. If the platinum surface is completely covered with adsorbed water, chemisorption of one propane molecule requires the displacement of one water molecule. In view of the large difference in the cross sectional areas of propane (about 35 Å2, estimated to be the mean value of cross sectional areas of n-butane and ethane4) and water (10.6 Å2 (ref. 4)) in physisorption, this seems to be caused by valency reasons rather than steric hindrance. At lower water coverages, the average number of displaced water molecules is naturally smaller.

At water coverages above a certain limiting value which corresponds to about one molecule of water for each platinum surface atom, the additionally adsorbed water is in a state in which it does not interfere with subsequently adsorbed propane.

The observations that the chemisorbed amount of propane is not changed by coverage of the surface with pre-adsorbed water and that only one water molecule is displaced by one propane molecule do not allow the conclusion that extensive dissociation does not follow the first propane chemisorption step. It may well be that instead of a simple dissociation occurring in the water-free case, we are dealing, in the case of water coverage, with a reaction of the chemisorbate with adsorbed water under simultaneous dissociation.

Optically Positive, Isotropic and Negative Lamellar Liquid Crystalline Solutions

The subject of the structure of liquid crystalline solutions of amphiphiles is of importance both with regard to the theory and technology of these substances and in relation to the liquid crystalline character of certain biological units, for example, cell membranes.

The aqueous lamellar liquid crystalline solution phase (neat phase, G) formed by many amphiphiles usually constitutes a positive uniaxial crystal. In this phase the amphiphile molecules form bimolecular leaflets with the hydrocarbon chains in contact (Fig. 1). The polar groups are associated with the water layers interposed between successive leaflets2.

In this model, the hydrocarbon chains, although commonly represented diagrammatically as lying normal to the planes of the lamellae, Fig. 1a, are believed to be in quasiliquid state and subject to thermal motion which, apart from the restriction imposed by their attachment to the polar groups in the lamellae, is similar to that in a liquid hydrocarbon of corresponding molecular weight. Except in certain circumstances considered here, the terminal attachment of the hydrocarbon chains to the polar groups will, however, lead to a predominating direction of carbon-carbon bonds across rather than along the lamellae -that is along rather than at right angles to the optic The predominating direction of carbon-carbon bonds along the optic axis provides the principal source

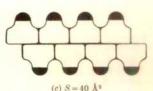

Fig. 1. Schematic representation of possible hypothetical territorial envelopes of amphiphile molecules in thermal motion in lamellae in which the effective area, S, per polar group is (a) 20 Å², (b) and (c) 40 Å²; in reality the envelopes will overlap.

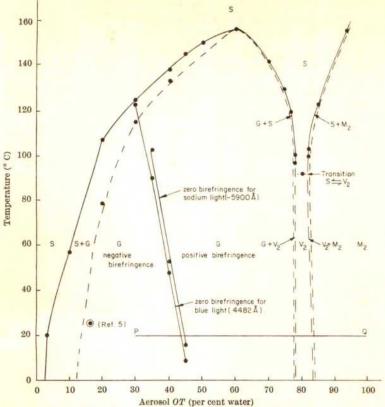

Fig. 2. Phase diagram for the Aerosol OT/water system. The boundaries indicated by broken lines are tentative. S is the mobile isotropic phase; G is the neat phase; M_z is the inverse middle phase; and V_z is the inverse viscous isotropic phase.

of the positive birefringence shown by the majority of G phases3.

It was noted by one of us (P. A. W.)4 that the stability of liquid crystalline G phases, over the wide ranges of concentration experimentally observed, indicates that changes in the effective area for each polar group must occur with changes in concentration although the order of the changes involved, as indicated by X-ray diffraction measurements⁵, was small. Definite, experimental

evidence of such changes, however, has been provided by more recent X-ray measurements. Thus with the potassium soaps of the n-fatty acids at 86°C, within the concentration limits of stability of the G phase, the effective area, S, for each polar group has been found to vary from 30.2 Å2 to 41.4 Å2.

In view of the quasi-liquid structure of the hydrocarbon regions of the G phase, it might be expected that if the directions of all the carbon-carbon bonds at any instant are resolved and summed as components normal to and parallel to the lamellae, then the ratio, X, of components normal to the lamellae against components parallel to the lamellae will tend to decrease with increase in the effective area, S, per polar group. Furthermore, if possible sources of birefringence other than preferred orientation of the carbon-carbon bonds are neglected, the positive birefringence of the G phase will decrease with decreasing values of X, becoming zero when X is about 0.5, and subsequently negative. X, however, is not necessarily a single-valued function of S, but at a given value of S, may vary with temperature. Thus if hypothetical values of S are taken as 20 Å^2 (close packing) and 40 Å2, possible hypothetical conformations of the territories occupied by amphiphile molecules in thermal motion within the bimolecular leaflets of the G phase may be

represented diagrammatically as in Fig. 1. Conformations (a) and $(b)^7$, in spite of the different values of S, would show The birefringence positive birefringence. of the conformation (c), in which the territories are statistically flattened with respect to the plane of the polar groups, would be less positive than that of (a) or (b). Forms intermediate between (b) and (c) and of consequently intermediate birefringence may

also be envisaged.

With amphiphiles containing a single n-alkane chain, the observed sign of birefringence of the lamellar phase is, apparently, always positive. From the experimental values of S found within the limits of stability of the lamellar phase produced with the fatty acid soaps⁶, this result is, on the basis of Fig. 1, not surprising. For branched-chain amphiphiles, however, molecular configurations within the G phase at which X could pass from > 0.5 at higher concentrations to <0.5 at lower concentrations, with increase in the effective area for each polar group2,6, would seem more

For example, with Aerosol OT (sodium sulpho-di(2-ethylhexyl) succinic ester) the two C₈ branches could be envisaged as forming a compact more acute-angled V (positive birefringence) at higher concentra-

tions which gradually opened to a more recumbent obtuse-angled V (negative birefringence) as the concentra-

tion was diminished and S increased.

In agreement with these considerations, we have recently observed a concentration-dependent change in the sign of birefringence with the aqueous G phase formed by this amphiphile and also by the corresponding potassium

With Aerosol MA (sodium sulpho-di(1,3-dimethylbutyl)

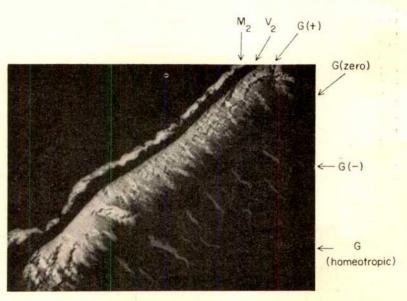

Fig. 3. Phase succession and change in birefringence produced by peripheral evaporation of the optically negative aqueous neat phase, G, formed by Aerosol OT (30 per cent weight). (\times 24.)

succinic ester), on the other hand, although the positive birefringence of the G phase at higher concentrations diminishes markedly with dilution, the phase breaks down at a concentration of about 37 per cent weight at room temperature, giving the isotropic micellar phase, before an actual change in sign of its birefringence has taken place.

Fig. 2 gives a tentative phase diagram which we have recently constructed on the basis of optical properties, nuclear magnetic resonance spectra and viscosity for a carefully purified sample of Aerosol OT. Fig. 3 illustrates the effect, as observed with a polarizing microscope, using white light, of allowing a sample of a negatively birefringent G solution of Aerosol OT (30 per cent weight) to undergo peripheral evaporation between slide and cover slip. In this way, an increasing concentration from the centre towards the edge of the sample is produced. Within the G phase itself, positive (outer, more concentrated) and negative (inner, less concentrated) zones may be distinguished which are separated by a narrow band not showing birefringence. The sign of the birefringence of the two zones was determined with a Red I compensator3. The textural features which extend across the two zones, in the one zone correspond to the fast direction, in the other correspond to the slow and in the intermediate band show zero birefringence (Fig. 3). The additional zones shown in Fig. 3 correspond to the phase succession $G \rightarrow V_2 \rightarrow M_2$ (ref. 8), indicated in Fig. 2 along the line PQ. The zone of null birefringence within the G phase in Fig. 3 corresponds in composition to the point of intersection of PQ and the line of zero birefringence for white light in Fig. 2.

It will be seen from Fig. 2 that for G solutions with birefringence close to zero the sign of the birefringence is sensitive to temperature. A rise of temperature produces an effect similar to that of an increase in concentration. A similar correspondence in the effects of increase in temperature or concentration is indicated by slight slopes of the $G-V_2-M_2$ phase boundaries in Fig. 2. results suggest a reduction in the effective area for each polar group with rise of temperature. This contrasts with the conclusions derived from X-ray diffraction measurements with the alkali-metal soaps, where an increase in area with rising temperature is found. The polar moiety of Aerosol OT (including the non-ionic ester carbonyl groups), however, differs considerably from the polar group of the soaps, and the interactions of the two types of group with the aqueous regions of the G phase may be affected differently by changes in temperature.

When a sample of the G phase about 5 mm in diameter, having any composition that gives negative birefringence (Fig. 2), is held between crossed polaroids and subjected to a gradual change in temperature which changes the sign of birefringence, a succession of interference colours can be observed with white light. The colours observed with white light at the points of zero birefringence as determined with sodium light or blue light are not black, but indigo blue and brownish yellow, respectively. These observations indicate that the Aerosol OT G phase, in the region of minimum birefringence, shows appreciable dispersion of the birefringence, so that the compositions corresponding to zero birefringence in Fig. 2 are, as shown, dependent on the wavelength of the light used (compare ref. 3, p. 338). Effect of Hydrogen Atom and Electron Scavengers on the Radiolysis of Ammonia Gas

Ammonia gas is decomposed by the action of ionizing radiations, hydrogen and nitrogen being the only products formed in significant amounts¹⁻³. Although some information about the nature of the primary processes in the radiolysis is available, chiefly as a result of mass-spectrometric studies4-8, the relative contributions of the different primary processes to the overall decomposition are not known. We report here an investigation aimed at determining the primary yield of hydrogen atoms in the radiolysis of ammonia and the contribution of ion neutralization to this yield.

It has been shown previously that the principal primary processes which are likely to play a part in the radiolysis of ammonia result ultimately in the formation of the radicals H and NH2 and it can be assumed that it is the reactions of these species which give rise to the products hydrogen and nitrogen. Thus the chief positive ions, formed by the processes (1) and (2)

$$NH_3 \land \land \rightarrow NH_3^+ + e^-$$
 (1)

$$NH_3 \land \land \rightarrow NH_2^+ + H + e^-$$
 (2)

react with ammonia by the fast reactions (3) and (4)

$$NH_2^+ + NH_3 \rightarrow NH_2 + NH_3^+ \tag{3}$$

$$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$$
 (4)

The ammonium ion persists (probably in the clustered form NH₄+nNH₃ (ref. 9)) until it is neutralized. Because negative ions are formed only to a negligible extent in pure ammonia7, the reaction of ammonium ions with electrons is the main neutralization process. Two possible reactions have been suggested³

$$NH_4^+ + e^- \rightarrow NH_3 + H$$
 (5)

$$NH_4^+ + e^- \rightarrow NH_2 + H_2$$
 (6)

Studies of the photolysis of ammonia10 indicate that the chief consequence of electronic excitation in the radiolysis will be N-H bond scission

$$NH_3 \wedge \rightarrow NH_2 + H$$
 (7)

The elimination of molecular hydrogen may be expected to occur to a minor extent10

$$NH_3 \land \land \rightarrow NH + H_2$$
 (8)

In order to measure the yield of hydrogen atoms and hydrogen from reactions (1) to (8), we used propane as scavenger. This reacts efficiently with free radicals but not with the other important intermediates, ammonium ions and electrons. The gases were irradiated with cobalt-60 γ-rays in sealed 'Pyrex' vessels. The dose rate, measured by the nitrous oxide dosimeter, assuming $G(N_2)=10$ molecules/100 eV (ref. 11), was 2×10^{15} eV/ml./min in ammonia at 760 torr, 20° C. The gaseous products, collected over traps at 77° K, were measured volumetrically and analysed mass spectrometrically.

Fig. 1 shows the dependence on temperature of the yields of hydrogen and nitrogen from pure ammonia, ammonia mixed with propane (1.5 mole per cent) and sulphur hexafluoride (0.3 mole per cent). In agreement with previous observations, the yields from pure ammonia are markedly dependent on temperature, and the ratio of the yields, hydrogen/nitrogen, is very close to the stoichiometric ratio, 3:1, which implies that the yield of hydrazine is negligible. In the presence of propane, the formation of nitrogen is greatly decreased and the hydrogen yield, $G(H_2) = 8.0 \pm 0.3$, is independent of temperature.

The marked depression of the nitrogen yield by propane can be accounted for in terms of reaction (9)

$$NH_2 + C_3H_8 \rightarrow NH_3 + C_3H_7 \tag{9}$$

which removes the NH2 radicals which in pure ammonia react to give nitrogen.

Hydrogen atoms react with propane

$$H + C_3H_8 \rightarrow H_2 + C_3H_7 \tag{10}$$

The yield of hydrogen is independent of the concentration of propane, from 1.5 to 6 mole per cent, showing that, at the concentrations used, reaction (10) competes favourably with any alternative reactions of hydrogen atoms. The yield of hydrogen $G(H_2) = 8.0 \pm 0.3$ is therefore a measure of the total yield of hydrogen atoms plus the molecular hydrogen formed directly—for example, by reactions (6) and (8). With propylene or benzene present (1.5 mole per cent), the yield of hydrogen fell to $G(H_2) < 0.8$. These additives remove free radicals by addition reactions so that the hydrogen observed is only that formed by molecular processes. The effect of propylene and benzene therefore suggests that the molecular yield is only a small fraction of the total primary yield.

Addition of sulphur hexafluoride to mixtures of ammonia and propane decreases the hydrogen yield by an amount $\Delta G(\hat{H}_2) = 3.9 \pm 0.3$ (Fig. 1). Sulphur hexafluoride captures electrons efficiently12, and it can be assumed that, in the presence of this additive, neutralization of the ammonium ion will involve reaction with the negative ion, SF₆-. The depression of the yield of hydrogen by sulphur hexafluoride is close to the yield of ammonium ions, $G(NH_4^+)$ = 3.8 (calculated from W = 26.5 (ref. 13)) and is therefore consistent with a mechanism in which neutralization of an ammonium ion by an electron results in the net formation of one hydrogen atom whereas neutralization by an SF₆- ion does not give any hydrogen atoms, for example,

$$NH_4^+ + SF_6^- \rightarrow NH_3 + HF + SF_5$$
 (11)

The effect of SF₆ in this system is similar to that previously observed in water containing scavenger concentrations of propane14. The residual yield of hydrogen from mixtures of ammonia with propane and sulphur hexafluoride

is presumably caused by reactions (2), (7) and (8). The observation that total yield of hydrogen from ammonia-propane mixtures, and the depression of this yield by sulphur hexafluoride, are independent of temperature, at least over the range 20°-200° C, strongly suggests that the primary reactions leading to hydrogen atoms in this system are not influenced by temperature. This finding is in conflict with an earlier suggestion¹⁵ that the extent of clustering of the ammonium ion, varying with temperature, might influence the ion-neutralization process and hence the extent of the primary decomposition.

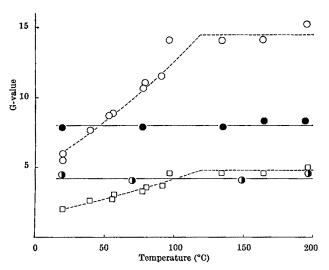

Fig. 1. Dependence on temperature of the yields from the radiolysis of ammonia in the absence and presence of scavengers. O, Hydrogen; D, nitrogen from pure ammonia; , hydrogen from ammonia + propane (1.5 mole per cent); , hydrogen from ammonia + propane (1.5 mole per cent) + sulphur hexafluoride (0.3 mole per cent). Total pressure, 1 atmosphere.

In the radiolysis of pure ammonia, the inter-reactions of the free radicals H and NH2 can result either in the formation of hydrogen and nitrogen or in the re-formation of ammonia. Without knowing the actual mechanism of the reactions involved, it is impossible to draw any firm conclusions from the total product yields about the extent of primary decomposition in pure ammonia. The results with propane as scavenger indicate, however, that the primary decomposition is independent of temperature. It is suggested therefore that the effect of temperature on the net decomposition of pure ammonia is the result of the competing reactions, which involve H and NH2 and, possibly, other intermediates formed from these radicals. This competition favours the re-formation of ammonia at low temperatures and the formation of hydrogen and nitrogen at high temperatures. The observed dependence on temperature of the yields would be consistent with an activation energy difference between the competing processes of about 2 kcal/mole (Fig. 1).

BIOLOGY

Molecular Theory of Sweet Taste

THE molecular feature common to the many different sweet tasting compounds has been sought for many years¹. For the sugars, it was proposed²⁻⁵ that the sweet unit is the glycol group, and that intensity of sweetness varied inversely with the degree to which glycol OH groups appear to be intramolecularly hydrogen bonded. It is now apparent that vicinal OH groups in the glycol unit need to be approximately gauche, or in a staggered conformation. Vicinal OH groups which are in the anti conformation apparently are too far apart to cause sweet taste. Glycol OH groups which are eclipsed probably participate in an intramolecular hydrogen bond which competitively inhibits interaction of glycol with the These steric features of sweet and nonreceptor site. sweet sugar glycol units are shown in perspective in Fig. 1. Glycol conformational parameters, and the gross conformation of pyranose and furanose rings, have been used to explain the varying sweetness of the sugars²⁻⁵.

A corollary to the thesis that sugar sweetness is inhibited by glycol intramolecular hydrogen bonds is that the primary mechanism for the sweet taste response is intermolecular hydrogen bonding between the glycol unit and the taste bud receptor site. The sweet unit of the sugars, that is the glycol unit, can be viewed as a bifunctional entity with an AH and a B component.

It is in this sense that we recognize a molecular feature common to the many compounds which taste sweet. In an AH, B system, A and B are electronegative atoms separated by a distance of greater than $2\cdot 5$ Å, but less than 4 Å. H is a hydrogen atom attached to one of the electronegative atoms by a covalent bond. Thus sweet tasting compounds must have a slightly acidic proton within a specific distance of an electronegative orbital. Usually A and B are either oxygen or nitrogen, but in certain cases one of them may be a carbon or chlorine atom or a centre of unsaturation. AH is a proton donor and B is a proton acceptor. Examples of sweet compounds and their AH, B system are shown in Fig. 2.

As an example of the sugars, β -D-fructopyranose is used. Probably all vicinal OH groups constitute sweet glycol units. The anomeric OH group, however, possesses the most acidic hydrogen in the molecule, and constitutes an AH moiety. In close proximity, and having free rotation, is the methylene OH group which could serve as the B moiety of the AH, B system.

Saccharine is the better known of the so-called "synthetic" sweetening agents. The AH moiety is the NH group. Two possible B moieties exist, the carbonyl oxygen atom and the sulphoxide oxygen atom. The latter is favoured, for pseudo-saccharine (enol-saccharine) does not taste sweet, and an AH, B system using the imide and sulphoxide groups also accounts for the sweetness of the cyclamates.

Chloroform is an example of a small molecule which is quite sweet. Because of the electron withdrawing power of the chlorine substituents, the carbon atom of the molecule is electronegative and the hydrogen atom is slightly acidic, and this constitutes the AH moiety. The electronegative chlorine atoms comprise the B unit to complete the bifunctional system.

Unsaturated alcohols, with the structure shown in Fig. 2, possess an OH group which is α - to a double bond, and consequently this OH group is slightly acidic. The unsaturated centre is an excellent proton acceptor site.

Alanine, whether D or L, is sweet¹. The $\rm NH_3+$ group in solution is an obvious AH moiety, and the COO-group would serve as the proton acceptor site. Other amino-acids have varying degrees of sweetness depending upon their size and the stereochemistry of the α -carbon atom.

An example of a nitro-benzene compound that tastes sweet is 1-propoxy-2-amino-4-nitrobenzene. The sweet-

Fig. 1. Sweet and non-sweet sugar glycol units.

NOT SWEET

Fig. 2. Compounds of various chemical classes and their common (AH, B) unit.

2-AMINO-4-NITROBENZENES

ALANINE

ness of the nitrobenzenes is greatly affected by substitution on the benzene ring. Thus it is apparent that the electron density at a specific point in the molecule will determine whether or not that molecule tastes sweet. As pointed out by Deutsch and Hansch⁶, electron donating groups para to the nitro group, or an electron attracting group meta to the nitro group, are related to sweetness. Our contention is that the ortho hydrogen is the proton of the AH, B system and the influence of other substituents on the nitrobenzene ring alter sweetness by changing the acidity (or H bonding power) of the hydrogen ortho to the nitro group. The importance of electron distribution in the aromatic ring is further emphasized by the significance of the Hammett σ value in the Deutsch and Hansch equation⁶.

Table 1. INTERATOMIC DISTANCES OF AH, B SYSTEMS IN REPRESENTATIVE

	177 t D			
Compound	AH	В	A-B distance (Å)	orbital distance (Å)
β -D-Fructopyranose	—он	-0-	3-5	2-4
Saccharine	NH	→0	2.5	3.0
Chloroform	-CH	Cl	1.9	2.8-3.2
1-Octene-3-ol (unsaturated alcohol) Alanine	—он — n н‡	H H C=C- C00-	3·0 3·0	2-4 2-4
1-Propoxy-2-amino- 4-nitrobenzene	ArH	→ 0	2.7	-

The A-B distance of sweet compounds does not appear especially important with respect to sweetness, as shown in Table 1. The AH proton-B orbital distance, however, is more significant. This is an average value of about 3 Å for all sweet compounds examined.

It follows that the receptor site is also a bifunctional unit similar in nature to the AH-B system of a sweet compound itself. Then the interaction between the receptor site and the sweet unit is a "concerted interaction" involving two simultaneous hydrogen bonds

Receptor
$$A - H \dots B$$
 Sweet unit

The interaction is neither a proton transfer nor an electrostatic interaction, but probably involves London dispersion, the principal element of hydrogen bonds7. It was proposed that the site could be the protein peptide bond3, but it could also be a protein amide group of glutamine or asparagine. Dastoli and Prices showed that a protein from bovine taste buds does indeed respond to sweet tasting compounds.

It would now seem that the complementary AH, B system needed to elicit sweet taste is a unit common to sweet tasting compounds which satisfies, regardless of chemical class, the spacial and hydrogen bonding require-

ments imposed by the receptor site.

Compounds with mixed tastes, but which are exceedingly sweet, such as saccharine and the cyclamates, also possess a hydrophobic bonding system which may account for the rapid "impact" time of chemicals when they elicit sweet taste. The hydrophobic bonding, how-ever, may also impart the intrinsic "bitter" afternote. Properties such as a hydrophobic nature may influence the intensity of sweetness, but the AH, B system described here is prerequisite for a compound to be sweet.

Hereditary Defect in Iron Absorption in Mice

Sex linked anaemia, which is hypochromic and microcytic1, was first observed in the male descendants of an irradiated mouse, and was shown to be an X linked recessive trait2. The gene symbol has been designated sla and its locus lies close to Tabby (Ta) and Brindled (Mo^{br}) in linkage group XX^2 .

The mechanism of the anaemia has been investigated in this laboratory using descendants of the original mixed strain, partially inbred by brother-sister matings, and on hybrids of the original mixed strain and the standard C57Bl/6 Jax strain, of the second to fourth backeross generations. In anaemic mice (hemizygous males and homozygous females), there is characteristic marked reduction in mean corpuscular haemoglobin concentration and mean cell volume. The anaemia is most severe in young animals, in which the haemoglobin concentrations range from 5 to 8 g/100 ml., and it regresses as the animals age3,4.

Siderocytes and sideroblasts are absent and histochemical studies of the iron stores reveal severe depletion in anaemic mice, particularly in the spleen4,5. Depletion of tissue iron stores is confirmed by direct chemical estimations of the total iron content of mouse carcasses

Table 1. TOTAL BODY IRON CONTENT Total body iron Genotype P content (μg/100 g)* Normal † 5.49 ± 0.27 (+/-)4.550 < 0.001 Anaemic ‡ (sla/ - and sla/sla) 3.72 ± 0.27

(Table 1). The anaemia responds to parenteral iron dextran in doses containing 0.5 and 5 mg of elemental iron^{3,4}. Serum iron concentrations and total serum iron binding capacity were determined and the results are given in Table 2; anaemic mice have a low serum iron concentration and increased iron binding capacity as is characteristic of iron deficiency in man?. Also consistent with iron deficiency is the presence of increased concentrations of free erythrocyte protoporphyrin8,8 as measured by the method of Grinstein and Wintrobe¹⁰ (Table 3).

Investigations with radioactive iron further support a hypothesis of iron deficiency in mice with X linked Tracer doses given intravenously are cleared from the plasma more rapidly than normal. Utilization of this tracer, as determined by its reappearance in the peripheral blood, is also more rapid than normal, and more complete (Table 4).

e 4. CLEARANCE OF INTRAVENOUSLY ADMINISTERED TRACER DOSES OF IRON-59 AND ITS REAPPEARANCE IN THE PERIPHERAL BLOOD

The iron content of the diet used (0.019 per cent by weight) is adequate to maintain normal haemoglobin concentrations and normal body stores in genetically normal littermates of anaemic mice4,5. Thus the possibility of malabsorption of iron as an explanation for X linked mouse anaemia has been investigated. The gross anatomical appearance of the small intestinal mucosa is normal in anaemic mice, but there is clear histochemical evidence of excessive iron deposition in the duodenal and upper jejunal mucosal epithelium, in contrast to the absence of stainable iron stores in the spleen and other organs of anaemic mice. The excess iron laid down in the mucosal epithelial cells is presumably shed as the epithelium is exfoliated. The retention of tracer doses of radioactive iron as ferrous sulphate, 5 days after oral administration by stomach tube, has been measured by whole body counting of normal and anaemic mice in a 'Tobor' (Nuclear-Chicago) large volume gamma scintil-

^{*} Means ± 1 S.E. † Twenty-eight normal male (+/-) mice. ‡ Eighteen anaemic male (sla/-) and seven anaemic female (sla/sla) mice.

Table 5. RETENTION OF TRACER DOSES OF IRON-59 5 DAYS AFTER ORAL

lation counter. Three doses of elemental iron have been tested-0·1 μg, I μg and 10 μg. With each dose the anaemic animals retain significantly less of the labelled iron than do the normal mice (Table 5).

Thus it seems that the anaemia of sla mice is caused by iron deficiency resulting from a defect in a genetically controlled step in the transfer of iron from the mucosal epithelial cells of the small bowel to the plasma compartment. The precise nature of this step and its relationship to the process of iron absorption as a whole remain to be elucidated.

This work was supported by grants from the National Institutes of Health, US Public Health Service. We thank Dr D. S. Falconer for the original stock of animals carrying the sla gene, and Miss Margaret Porter and Mrs Betty Murphy for technical assistance.

Stimulation of Yolk Deposition in an Ichneumonid Parasitoid by feeding Synthetic Juvenile Hormone

Some ichneumonid parasitoids need to feed on their hosts for egg maturation. Leius¹ found significant differences in fecundity of the parasitoid Scambus buolianae (Htg.) when it was fed various species of lepidopterous hosts, and he has attributed these to variations in the chemical composition of the haemolymph of the different hosts. Exeristes comstockii (Cresson) is another example of an ichneumonid in which full maturation of ovaries occurs only when fed on a host or a synthetic diet2. development in a number of insects is regulated by endocrine activity of the corpus allatum³, and compounds like farnesol can mimic the activity of the corpus allatum hormone in promoting yolk deposition when applied topically to decapitated *Rhodnius*⁴ and allatectomized *Periplaneta americana*⁵. The following experiments were

conducted to determine (1) whether feeding E. comstockii sugar solution containing farnesol or its derivative farnesyl methyl ether, as well as topical application of the latter, would promote maturation of the ovaries, and (2) whether farnesyl methyl ether added to a synthetic diet would increase egg deposition.

Separate groups of from ten to twenty newly emerged and mated female E. comstockii were fed a 10 per cent solution of sucrose only, 0.1 per cent farnesyl methyl ether in 10 per cent solution of sucrose, 0.3 per cent farnesol (Calbiochem) in 10 per cent solution of sucrose and a chemical diet². All diets contained 0·1 per cent of 'Tween 80' as emulsifier. After 9 days, females from each group were dissected and the number of eggs more than 1.2 mm long in the ovaries was counted. These numbers were transformed to $\sqrt{x+0.5}$ to correct for heterogeneous variance and were then compared by t tests. The mean number of eggs in the ovaries of females fed farnesyl methyl ether in sucrose was 18.3 ± 0.3 , whereas that of females fed chemical diet was 7.6 ± 0.6 . This difference was significant (P < 0.01). In the females fed sucrose only and those fed 0.3 per cent farnesol in 10 per cent of sucrose the mean numbers of eggs in the ovaries were 2.2 ± 0.4 and 2.8 ± 0.4 , respectively. These means are significantly lower than those of females fed farnesyl methyl ether and chemical diets, but are not different from each other.

To compare the effect of topical application of farnesyl methyl ether with that of feeding, we tested three groups of eleven mated females treated as follows: one had pure farnesyl methyl ether applied directly to the abdomen with a small brush and was then fed 10 per cent sucrose solution; a second was fed a solution of 0.1 per cent farnesyl methyl ether in 10 per cent sucrose solution; and a third was fed sucrose solution only. Ovarian development was assessed after 9 days. The mean number of eggs in the ovaries of those fed farnesyl methyl ether in sucrose was significantly higher than that of those treated with farnesyl methyl ether externally $(12.7 \pm 0.9$ against 8.3 ± 1.1 ; P < 0.01), and both treated groups had significantly more eggs in ovaries than the sugar-fed control (2.8 ± 0.8) . The external treatment was applied once only at the start of the experiment, whereas treatment in the food was continuous; this might account for the greater ovarian development observed in the feeding treatment.

To determine whether females fed 0.1 per cent farnesyl methyl ether in sucrose would oviposit a greater number of eggs than those fed sucrose alone and, similarly, if females fed 0.1 per cent farnesyl methyl ether in synthetic diet would oviposit more than females fed diet alone, four groups of fifteen newly emerged and mated females were caged individually and each group fed one of the foregoing diets. Coddled Galleria mellonella L. larvae were offered daily in wooden blocks, so that the parasitoid could not feed on them, but could oviposit on them2. Egg deposition was recorded for 2 weeks.

Females fed farnesyl methyl ether in 10 per cent sucrose solution oviposited more eggs than females fed sucrose alone $(3.7 \pm 0.7 \text{ against } 0.7 \pm 0.3; P = 0.02)$. The mean number of eggs from each female fed synthetic diet and farnesyl methyl ether, and fed synthetic diet alone, was 16.2 ± 4.3 and 21.4 ± 4.4 , respectively. These means do not differ significantly from each other, but are significantly higher than the means for females fed sucrose alone and for those fed sucrose and farnesyl methyl ether.

It was previously believed that adult ichneumonid parasitoids feed on host tissues because they bring very low nutritional reserves into the adult stage for maturation of the ovaries. The results reported here show that this view is not completely correct. E. comstockii evidently carries enough nutritional reserves for full ovarian maturation without recourse to protein feeding. These reserves can be utilized for yolk deposition if the insect is treated with farnesyl methyl ether, which mimics the activity of the corpus allatum. This observation is similar to that of Johansson⁶. He found that implantation of an active corpus allatum induced egg development in starved females of the milkweed bug, Oncopeltus fasciatus. It is interesting to note that the chemical is especially effective for E. comstockii when presented in the food.

Although increased egg deposition occurred in females fed with farnesyl methyl ether as compared with females fed sucrose alone, only about a quarter of the eggs developed in the ovaries was actually deposited. This suggests that although the chemical stimulates yolk deposition, it is unable to stimulate those factors that regulate oviposition. Addition of protein in the diet stimulates both yolk deposition and oviposition. Thus an additional mechanism controlling oviposition is present and it is undoubtedly linked with nutritional factors.

We thank Messrs Hoffman La Roche, Basle, Switzerland, for the farnesyl methyl ether.

Artificial Feeding Technique for Rhipicephalus appendiculatus and the Transmission of Theileria parva from the Salivary Secretion

Nuttall and Hindle 1 were the first to suggest that Theileriaparva, which is the causal organism of East Coast fever in cattle, develops to the infective stage in its common tick vector, Rhipicephalus appendiculatus, only after the ingestion of blood by the tick. This finding was supported by Cowdry and Ham² and, more recently, by Martin et al.³, who found the greatest numbers of parasites in salivary glands after 4 days of feeding although they did observe parasites in the glands after as little as 24 h. Infectivity therefore seems to be dependent on the feeding process.

During an attempt to study this phenomenon and to isolate the infective stages of T. parva which are secreted, we have found that adult R. appendiculatus partially fed previously on rabbits or cattle will absorb blood from capillary tubes placed over the hypostomes or capitula and that after 2 h the residual blood pool may be infective when injected into cattle.

Nymphal R. appendiculatus derived from the experimental stock were fed on cattle which were either uninfected or carrying patent infections of the Muguga strain of T. parva (> 10 piroplasms/1,000 red blood cells⁴). After moulting, equal numbers of males and females were

placed in calico bags on the ears of rabbits or cattle4. They were examined after 24 h and again after 48 h, and as they attached the ticks were marked with cellulose paint. They were considered as having fed for one day if they had attached during the previous 24 h and those ticks which did not attach within 48 h were discarded. After the initial feeding period (usually 4 days) the ticks were detached from the skin of the host and restrained, ventral surface uppermost, on wads of 'Plasticine'. A glass capillary tube (mean diameter 1·17 mm), slightly rounded at the tip and containing about 0.05 ml. of heparinized or defibrinated blood, serum or plasma, was placed loosely over the mouthparts of the ticks, and was supported at about 30° above the horizontal by a further wad of 'Plasticine'. In early experiments, only the hypostome was enclosed, but when the entire capitulum was inserted into the capillary tube, palpal movements and feeding occurred equally well. A temperature of approximately 27° C (24°-29° C) was maintained by a bench light placed overhead.

The capillary tubes, which were manufactured to a standard specification, were calibrated so that the volume of fluid absorbed by the ticks could be assessed by measuring the length of the column in the tube Forty tubes were calibrated in this way and a mean value of $1.08 \text{ mm}^3 \equiv 1 \text{ mm column length } (S.D. 0.036) \text{ was}$ obtained. A correction for the loss caused by evaporation under the same conditions was obtained from tubes sealed at one end and filled with blood or serum. volumes of fluid consumed in 24 h by two batches of adult ticks fed by this method on different substrates are given in Table 1. Each value is the mean for ten ticks. The greatest volume was consumed when serum or plasma was offered. Female ticks initially fed on cattle did not feed as well as those from rabbits. This may be the result of different mating behaviour on the two hosts, which in these experiments may also be related to the age of the ticks. Among those which had fed on the rabbit, certain individuals fed particularly well which may have been the result of early mating, for Gregson⁵ has shown that the rate of engorgement in Dermacentor andersoni is related to mating. Most of the females removed from the host at this stage, however, do not seem to engorge completely. Nevertheless, some individuals which have been fed for periods up to 7 days on capillary tubes have proceeded to lay viable eggs. To maintain feeding during these extended periods it was necessary to replace the tube of blood at intervals because it became occluded by the hypostomal cement. When fed on blood, both sexes excreted from the anus spherical droplets which rapidly hardened and were hollow. The droplets of excreta when smeared on a microscope slide were seen to contain numbers of undamaged red blood cells. When blood infected with T. parva was used, some piroplasms within the erythrocytes were seen to pass intact through the tick.

To demonstrate the infectivity of the residual feeding pool, batches of twenty to twenty-six adult ticks infected with T. parva were withdrawn from rabbits after 4 days of feeding. They were then fed on tubes of uninfected heparinized or defibrinated bovine blood or serum for 2 h. The residual fluid in the capillary tubes was pooled, made up to 1 ml. with uninfected bovine blood or serum,

Table 1. YOLUME OF BLOOD SUBSTRATES CONSUMED IN 24 h BY ADULT R. appendiculatus

			Mean volume and range consumed (mm³/tick) Substrate						
Initial feed	Batch No.	Age at attachment	Sex	Serum	Plasma	Defibrinated blood	Heparinized blood		
4 days on rabbit	971 (infected)	2 weeks	Male Female	$ \begin{array}{r} 5.8 \\ (0.0-20.5) \\ 10.3 \\ (1.2-41.4) \end{array} $	6·3 (2·2~18·1) 8·6 (0~51·7)	1·0 (0·0-3·1) 4·2 (0·0-13·0)	$^{1\cdot 1}_{(0\cdot 0-2\cdot 9)}\ ^{4\cdot 3}_{(0\cdot 5-19\cdot 8)}$		
5 days on bovine	207 (uninfected)	15 weeks	Male Female	13·2 (1·3-35·4) 4·1 (0·0-14·0)	8·4 (0·3–19·2) 3·7 (0·0–10·7)	5·3 (1·3-16·1) 1·8 (0·0-6·0)	$ \begin{array}{c} 3.7 \\ (0.0-10.0) \\ 2.8 \\ (0.0-7.1) \end{array} $		

and injected intradermally into the base of the right ear of a susceptible steer.

So far, eleven animals have been injected with the residual feeding pool in this way. Three out of five animals receiving heparinized blood developed fever, and hyperplasia of the lymph nodes in which schizonts of T. parva were found; one out of four animals receiving defibrinated blood also developed a similar infection, while neither of the two which received serum pools reacted. All four infected animals developed piroplasms typical of T. parva in the blood and two of them died.

Chabaud⁶ used a similar artificial feeding technique for some species of Ixodidae (including R. sanguineus), and Gregson 7-9 used the method to study salivation and feeding in D. andersoni. Both these authors found it necessary to spread the palps, whereas this does not seem to be so for the feeding of R. appendiculatus. We shall use this technique to obtain further quantitative data on the effects of sex, temperature and substrate on feeding activity.

The infectivity of the residual pool is of particular It indicates that salivation occurs during capillary feeding for as short a period as 2 h, and offers a method of obtaining the infective stages of T. parva. Further experiments are in progress to increase the efficiency of the method and to study the properties of the infective stages so obtained.

We thank Mr K. P. Bailey, who maintained the colonies of infected and normal R. appendiculatus and made available the ticks used in this study, and a number of colleagues, notably Professor W. F. H. Jarrett and Dr J. K. H. Wilde, for their helpful suggestions. This work was carried out during the assignment of one of us (L. P. J.) by the Food and Agriculture Organization of the United Nations to the East African Veterinary Research Organization.

MICROBIOLOGY

Mycobacteriophages isolated from Human Sources

THE isolation of mycobacteriophages from stool and resection specimens of patients with tuberculosis or sarcoidosis was first described in 1961 (ref. 1). Further results obtained during the past 5 yr in isolations of mycobacteriophages are reproduced in Table 1. These figures show that healthy persons rarely harbour mycobacteriophages in their intestinal tract, whereas stool and resection specimens of patients with tuberculosis or sarcoidosis frequently contain these mycobacteriophages.

Table 1. ISOLATION OF MYCOBACTERIOPHAGES FROM STOOL AND RESECTION SPECIMENS

Specimen Tuberculosis Sarcoidosis Healthy persons Stool 76/155 (49 per cent) 73/190 (38.4 per cent) Biopsy or 41/130 (31.5 per cent) 48/86 (55.8 per cent) resection 2/121 (1.6 per cent)

This communication deals with attempts to demonstrate mycobacteriophages in serum samples collected from normal persons and from patients with pulmonary tuberculosis or sarcoidosis. The diagnosis of tuberculosis was always confirmed by the isolation of M. tuberculosis. The diagnosis of sarcoidosis was established on clinical grounds, X-ray evidence, the histopathological examination of biopsies of lymph nodes, lungs or bronchial mucosa, and/ or Kveim tests.

Bacteriophages were isolated by successive passages of the serum in the RVB 6 medium described by Redmond and Ward², and from which the albumin V fraction had been omitted. The media were inoculated either with strain $H_{37}Rv$ or ATCC 607 before the addition of the patient's serum, which was added to a final concentration of 10 per cent. When a patient was on antituberculosis drug therapy or had received therapy shortly before the blood was taken, his serum was added to a culture of strain R 100 which is resistant to 100 $\mu g/ml$. of streptomycin and to 10 µg/ml. of isoniazid. After each passage in enriched medium, the culture filtrates were essayed 'spotting' on mycobacterial indicator strains3. Plaques were isolated and passaged once in liquid medium. Filtrates, adjusted to contain 1 routine test dilution in particles lytic for the strain on which the bacteriophage had been propagated, were spotted on other indicator strains to establish the lytic spectrum of each bacteriophage close to the time of its isolation.

No mycobacteriophages were isolated from serum samples of fifty-one healthy persons or from fifty-two with tuberculosis. Ninety-nine sera were examined from patients with pulmonary sarcoidosis. Of these, twentyfour had been collected in Montreal hospitals; thirty four in the Epidemiology Division of the Department of National Health and Welfare, Ottawa, and forty-one in the Sanatorium Hochenschwand in Germany. Eighteen of the cultures of sera collected in the Montreal area (75 per cent), fifteen of the sera from the Ottawa area (44 per cent) and twenty of the sera from Germany (49 per cent) contained particles lytic for mycobacteria.

The host range of the mycobacteriophages isolated from the sera of patients with sarcoidosis was limited in two phages to the strain ATCC 607. All other bacteriophages had a wide host range including virulent tubercle bacilli, atypical and saprophytic mycobacteria.

The frequent isolations of mycobacteriophages from patients with sarcoidosis and the previously reported absence of phage neutralizing antibodies in the sera of these patients suggest a state of "anergy" in these persons which parallels their non-reactivity towards tuberculin and PPD after natural exposure to tubercle bacilli or after BCG vaccination5.

Tuberculin reactions are sometimes depressed during viral infections. In recent experiments, it has been observed that BCG-vaccinated guinea-pigs which react strongly to intracutaneous tuberculin show a depression of the tuberculin reaction after the intraperitoneal inocula-This depression tion of mycobacteriophage lysates. exceeds the 5 week period during which mycobacteriophage particles can be isolated from their liver, spleen or the circulating blood.

This observation suggests that the "anergy" of patients with sarcoidosis towards tuberculin may result from the viraemia; or both phenomena (the suppression of this delayed type of allergy and the absence of phage-neutralizing antibodies which results in the long survival of the phage particles) may stem from the same (unifactorial or multifactorial) immunological defect.

There have been many studies of serum antibody concentrations in patients with sarcoidosis after immunization with typhoid-paratyphoid vaccines or other bacterial No defect in the production of circulating antigens. antibodies to these antigens could be detected. Kallings and Loefgren, however, reported the absence of phage neutralizing antibodies to coli T2 bacteriophages in the sera of 22 per cent of patients examined, while the sera of healthy persons contained appreciable titres of these "natural" antibodies. antibodies.

The mycobacteriophages which were isolated from the sarcoid tissue or from the sera of patients with sarcoidosis could have originated from the lysogenic mycobacteria which were demonstrated in the tissue biopsies of these patients⁸ but which were never demonstrated in their sera. These bacteria, or phage-infected mammalian cells, may be the reservoir for phage particles that are released into the circulation.

We thank Dr A. R. Armstrong of the Hamilton Health Association for a culture of strain R 100. We also thank Dr John W. Davies and Miss Mary MacBeth, of the Epidemiology Division, Department of National Health and Welfare, Ottawa, and Professor K. Wurm of Hochenschwand, Germany, for samples of serum and case histories.

Degradation of Salicylate by Aspergillus niger

SALICYLATE continues to be a leading cause of accidental poisoning in the United States; in 1964 there were more than 16,000 cases of accidental aspirin ingestion among all age groups, accounting for 25.8 per cent of all accidental poisonings reported1. Existing methods for the treatment of salicylate poisoning are aimed at alkalinization of the urine and extrarenal removal of the drug^{2,3}. The natural elimination of salicylate in man is a slow process. The average half-life of a single 1 g dose of aspirin is reported to be 6 h (ref. 4), and high doses have given half-life values up to 19 h (ref. 5). Administration of salicylate labelled with carbon-14 to man's has given the following metabolites (here reported as average mean values): free salicylate 61 per cent; salicylic phenolic glucuronide 22 per cent; salicyluric acid 8 per cent; salicylic acyl glucuronide 5 per cent; and gentisic acid 1 per cent. The conjugates of salicylic acid are less diffusible across cell membranes and thus have given higher clearances7. Furthermore, the excretion of salicyluric acid after administration of acetylsalicylate or salicylate is limited by the ability to conjugate salicylate with glycine rather than the excretion capacity of the kidneys8.

Metabolic manipulation aimed at converting free salicylate to conjugated forms may be useful as a third therapeutic approach to the treatment of salicylate toxicity. Theoretically, this could be accomplished by the use of specific enzymes isolated from organisms and capable of degrading salicylate. Although enormous obstacles might still have to be overcome before any such enzymes could be used in vivo, the potential value of such an enzyme justifies its investigation. This communication presents the results of preliminary studies using fungi to degrade the salicylate molecule.

Table 1. Growth of funci in still and shake culture on a salioylate medium

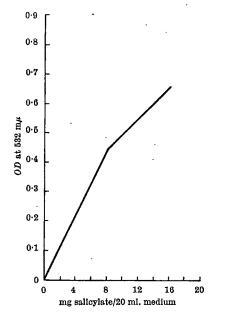

Organism	Still culture (days)				Shake culture (days)			
	1	2	3		1	2	3	
Trichoderma species (I-193)		_	+ 8			+ 6	+ ,	
Rhizopus nigricans (314 +)	-	_	_			-	-	
Dactylium dendroides (I-108)	-		_		_	_	_	
Cladosporium species (I-75)	_	_		•	_	_	_	
Cladosporium cladosporiodes (I-83)	_	_			_	- ·	_	
Saccharomyces cerevisiae (1)	_	_				_	_	
Aspergillus niger (10)	-	+8	+ m		-	+ m	+h	
Uninoculated control	-	_	_		_	_		

All cultures used were obtained from the Ohio State University stock culture collection. The stock culture number is in parentheses. The symbols $+_8$ (slight), $+_m$ (moderate) and $+_h$ (heavy) refer to visual observation of the growth of the fungus in culture.

All studies were carried out in synthetic liquid media with the following composition: 1 g of NH₄NO₃; 1.0 g of KH₂PO₄; 0.5 g of MgSO₄·7H₂O; 0.13 g of CaCl₂; 0.1 g of NaCl; and 0.01 g of Fe₂(SO₄)₃·nH₂O made up to 1 l. Sodium salicylate (NaC, H,O), the only source of earbon, was added in a concentration of 1 mg/ml. and dispensed in 20 ml. samples in 125 Erlenmeyer flasks. The final pH was 4.5. Flasks were inoculated with 0.2 ml. of water suspension of spores from a slant culture of the organism (10 ml. of sterile distilled water/PDA agar slant). Incubation was at 20°C in still culture or as shake cultures on an Eberbach reciprocating shaker (100 oscillations/min). Salicylate degradation was measured according to a slight modification of the methods of Trinder⁹ and DeMarco and Marcus¹⁰ utilizing a Bausch and Lomb 'Spectronic 20'.

Table 1 shows representative data about the growth of seven organisms on still and shake cultures. Two organisms which grew in a medium containing salicylate as the sole carbon source were Aspergillus niger and a species of Trichoderma. Aspergillus niger was selected for further tests because of its rapid growth in shake culture and because it has been intensively studied and approved by the US Federal Drug Administration.

Fig. 1 presents standard curve data obtained from the addition of 5 ml. of a solution of 0.05 per cent FeCl₃ made up in 0·1 normal HCl to 5 ml. of a 1:10 dilution of the salicylate medium. Readings were taken at 532 mu 5 min after formation of the ferric salicylate complex, against a suitable reagent blank. The system obeyed Beer's law at the lower concentrations of salicylate used (1-8 mg).

. Standard curve obtained from addition of ferric chloride solution to the sodium salicylate medium (details in text).

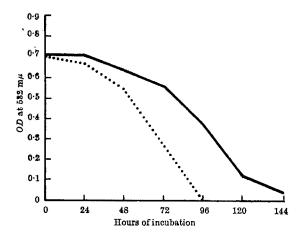

Fig. 2. Salicylate degradation by Aspergillus niger in still (----) and shake (.....) culture.

As shown in Fig. 2, the degradation of salicylate by Aspergillus niger occurred in both shake and still cultures. There appeared to be an initial lag phase of approximately 24 h followed by an exponential utilization of the salicylate. In one series of flasks, salicylate had disappeared as early as 76 h after inoculation in shake culture. We are now trying to isolate the enzyme or enzymes from Aspergillus niger which are responsible for this rapid degradation of salicylate, for use in investigations in mammalian systems.

This investigation was supported by a grant from the US National Institutes of Health.

CYTOLOGY

Variation in the Human Chromosome Number

INCREASED aneuploidy has been described in cultured human peripheral blood cells, beginning in the sixth decade of life for females, and in the seventh decade of life for males1. This increased aneuploidy has been attributed largely to the presence of cells containing forty-five chromosomes, with an XO sex chromosome constitution.

During cytogenetic studies of atomic bomb survivors of Hiroshima and Nagasaki2,3 we have been able to evaluate the hypothesis of selective loss of the sex chromosomes with increasing age. We have now counted and examined the chromosomes of more than 18,000 cells from 329 patients, aged between 20 and 88 yr. Our results indicate that variation in the chromosome number occurs within a very narrow range throughout the adult years. The presence of cells with forty-five chromosomes is largely responsible for the existing deviation from the modal number, and chromosome loss seems to be neither completely random nor entirely related to chromosome

The population studied was selected from the Adult Health Study sample, a group of nearly 20,000 people who are examined every 2 yr in the Hiroshima and Nagasaki clinics of the Atomic Bomb Casualty Commission. Characteristics of this sample have been given elsewhere4. For cytogenetic study, index patients were selected from those who are estimated to have received 200 rads or more of mixed gamma and neutron radiation at the time of the atomic bombings. A control was selected for each index patient, matched by age, sex and city, from those who were over 3,000 m from the atomic bomb hypocentres. The controls are estimated to have been exposed to less than 1 rad. Any person with a history of malignant disease was excluded from the study, as were those with a history of radiation therapy, radioisotope exposure or those who had evidence of a viral exanthem on physical examination. Those patients with a history of diagnostic X-irradiation, exclusive of chest X-rays, in the preceding 12 months were also excluded. In all cases, peripheral leucocytes were cultured according to the method of Moorhead et al.5, and were collected between 66 and 72 h of culture.

In 20-49 yr old patients the chromosomes were counted only in the first thirty cells examined, although whenever possible a total of 100 cells was examined for the presence of structural aberrations. In patients more than 50 yr old, an attempt was made to both count and analyse 100 cells each. For these older patients, whenever cells with missing or additional chromosomes were encountered an attempt was made to classify such chromosomes by group. Cells were selected under low power (x100), according to (a) their apparent integrity and (b) the quality of chromosome spreading. Once considered to be suitable, a metaphase was included in the study, whether or not structural alterations were present. In determining the chromosome count of a cell, the number of centric chromosomes alone was used.

The blood samples were processed, and the slides were read, without technician or observer knowledge of the age, sex or exposure status of the patients.

There was no systematic difference in the distribution of chromosome number between cells of the heavily exposed and those of the controls, and so the data for these two groups have been combined. As shown in Table 1, 135 males and 194 females were studied cytogenetically. In the 74 males and 114 females who were between 20 and 49 yr old, from 94.4 to 97.8 per cent of cells counted contained forty-six chromosomes. Most aneuploid cells were hypomodal, with 45-chromosome cells predominating.

Among the 141 persons between 50 and 88 yr old, sixty-one were males and eighty were females. Fifty-three of the 141 were more than 70 yr old. As seen in Table 1, the percentage of cells with forty-six chromosomes ranged, in this older group, from a low of 94·1 in males older than 70 yr, to a high of 96.9 in females in the seventh decade of life. The lack of a consistent trend with age is shown graphically in Fig. 1. There was little difference between the sexes in terms of aneuploidy in old age; and there was, further, no pronounced tendency for males or females to show increased aneuploidy late in life as compared with the earlier years.

Fig. 1 also shows the distribution of the percentage of cells with forty-five chromosomes by sex and age of the patients at the time of examination. While a total of 422 cells with forty-five chromosomes was found, 100 of

The X chromosomes were here grouped with the Cs; the Y chromosomes with the Gs.

* Expected values assuming random loss.

† Expected values assuming probability of loss to be inversely proportional to size.

these were from patients younger than 50 yr and no attempt has been made to identify the missing chromosome. This was done only in the remaining 322 forty-five chromosome cells seen in the 141 patients who were more than 50 yr old. In 264 instances, the missing chromosome could be identified by group.

The distribution of these cells is shown, separately by sex, in Table 2, together with expected numbers based on two different sets of assumptions regarding loss. First, if loss were entirely random, then the probability of loss from each group would be determined completely by the number of chromosomes in the group. It is apparent that our observations do not conform to the pattern expected with random loss, there being generally a lack of cells missing the larger chromosomes and a surfeit of those missing the smaller chromosomes. The pattern suggested that the likelihood of chromosome loss may be inversely related to chromosome size, and another set of expected numbers was derived on this assumption.

[Fig. 1. Percentage of cells with forty-six and forty-five chromosomes, by age and sex of patients. •, Male; O, female.

Specifically, we assumed that there are k chromosomes identified by categories, X_i , $i=1,\ldots,k$. If we let Y_i (>0) denote the length of chromosome X_i , and $P(X_i)$ denote the probability of loss of a single chromosome from category X_i , then the hypothesis of loss being inversely related to size states that:

$$\frac{P(X_i)}{P(X_j)} = \frac{Y_j}{Y_i} \text{ for all } i \text{ and } j$$

For example, if an A_3 chromosome is 7·1 per cent of the haploid autosomal complement and if each D is 3·5 per cent of the complement⁶, then the probability of loss of a D group chromosome in a male is 0·045, while the probability of an A_3 being lost is 0·023. That is, a D group chromosome is twice as likely to be lost as an A_3 , because it is half the size of an A_3 . Using this assumption, together with the fact that the probabilities must

add up to $1.0 \binom{k}{i=1} P(X_i) = 1$, it is not difficult to show that the probabilities for the loss of individual chromo-

that the probabilities for the loss of individual chromosomes are given by

$$P(X_i) = \left[Y_i \sum_{j=1}^k Y_{j-1}\right]^{-1}, i=1,\ldots,k$$

Probabilities were calculated using the estimated lengths given in the report of the Chicago conference. The probabilities for individual chromosomes within the appropriate chromosomal groups were then summed. As seen in Table 2, while the expected numbers thus derived improved the agreement with the observed distribution over that given by the random loss expectations, the fit is still not a good one for either sex. In males, G group chromosomes, which here include Y chromosomes, were lost far more often than this hypothesis would explain. In females, G group chromosomes, which here include the two X chromosomes, were lost more often than expected, as were Bs, Ds and Gs. The largest contributors to the lack of fit, in females, were, however, the F, A and D groups, in that order.

These results suggest that the proportion of cultured leucocytes which contain the normal forty-six chromosome complement is relatively constant from the third decade of life. While the Edinburgh group, even in their 3 day cultures, have found from 7 per cent aneuploidy in elderly males to 13 per cent in elderly females, we have found that for both sexes, at all ages, the proportion of aneuploid cells is between 2 per cent and 6 per cent. None of our 329 patients were chromosomal mosaics, nor did any of them have a modal chromosome number other than forty-six. Thus our population was, in terms of chromosome number, an essentially normal one.

While a small percentage of non-forty-six-chromosome cells were hypermodal, with no discernible pattern of addition, most were hypomodal and contained forty-five chromosomes. It seems that loss of a single chromosome is not entirely a random phenomenon. It also appears that small size alone cannot explain the observed patterns of chromosome loss.

With respect to the hypothesis of selective sex chromosome loss, our findings show a marked excess of G group chromosome loss in males which cannot be explained by either the random loss or loss by size hypothesis. G group loss in females, on the other hand, is not consistent, either in magnitude or direction, for the two postulated hypotheses. Thus it seems likely that the probability of loss of a given chromosome is influenced by a number of factors, acting either separately or in combination. These could include a random component as well as the size of the chromosome and the position of the chromosome on the spindle during cell division. To these must be added, in males, the tendency for G group chromosomes, which include the Y, to be lost because of some other, perhaps more selective, mechanism. There may also be prepara-

tive, or other factors, which are characteristic of the laboratory in which the data are collected.

Our data must be qualified by indicating that the culture time of $66-72 \text{ } \hat{\mathbf{h}}$ was sufficiently long to enable both first and second division products to make their appearance. The 2 day culture system which we are now using7 may further reduce the proportion of aneuploid cells and give a more representative picture of the in vivo situation. Certainly this should be the case if chromosome loss occurs primarily in tissue culture. But if loss occurs predominantly during an in vivo division, the proportion of an uploid cells should vary little with culture time.

PATHOLOGY

Urinary Excretion of 3,4-Dimethoxyphenylethylamine in Parkinson's Disease

There is considerable evidence for the involvement of dopamine in the extrapyramidal system and in its disorders¹⁻⁴. The methoxy derivative of dopamine, 3,4-dimethoxyphenylethylamine (DMPEA), as measured by the paper chromatographic method of Friedhoff and Van Winkles, was excreted in a large concentration in the urine of patients suffering from Parkinson's disease⁶. On the other hand, DMPEA caused a hypokinetic and rigid syndrome in experimental animals7,8, thus further increasing the significance of this compound in extrapyramidal disorders.

It was reported originally that DMPEA determined by this method was unique to the urine of schizophrenic patients, suggesting a close relationship between the compound and the disease^{5,9,10}. It was found, however, that DMPEA was also excreted by non-schizophrenic, normal patients¹¹, and later attempts to detect the compound have been unsuccessful^{12,13}. Furthermore, doubt has been cast on the identification of the compound as DMPEA by the methods used^{14,15}. To increase the sensitivity of the identification of DMPEA, the paper chromatographic system was combined with a fluorimetric examination and many of the pink spots of the paper chromatographic method did not fluoresce^{14,16}.

We have investigated urinary excretion of DMPEA in patients suffering from Parkinson's disease by this new, more accurate method. We studied twenty patients

(eleven female and nine male) with Parkinson's disease, mean age 59 yr. Nine patients (six female and three male) suffering from various neurological diseases without extrapyramidal symptoms were the control group; their mean age was 45 yr, and none was known to have renal or liver disease.

A 24 h urine specimen was collected in hydrochloric acid and deep-frozen until it was analysed. DMPEA was separated by paper chromatography¹⁴ and then examined fluorimetrically by the method of Bell and Somerville¹⁸.

The mean excretion of DMPEA was $4.4 \pm 1.2 \mu g/24 h$ in subjects with Parkinson's disease and 6.8 ± 3.6 $\mu g/24$ h in the control subjects. No DMPEA was detected in two of the nine controls or three of the twenty cases with Parkinson's disease. There was no significant difference between the groups in their excretion of DMPEA. There was also no clear correlation between excretion of DMPEA and the severity of akinesia or rigidity of the parkinsonian patients.

These results show that DMPEA is not unique to the urines of schizophrenic patients as has been suggested5, because it was excreted by non-schizophrenic patients suffering from Parkinson's disease and other neurological diseases. DMPEA treatment had no psychogenic properties17, which casts doubt on the assumed relationship between the compound and the disease. Furthermore, it has been suggested that DMPEA is of exogenous origin 11,12 and that psychotropic drug therapy rather than the disease influences the occurrence of pink spot in the paper chromatographic system used18.

These results do not confirm the views that there are clear changes in the urinary excretion of DMPEA in patients suffering from Parkinson's disease. This difference of results may reflect differences in the methods used and in the population of parkinsonian patients. Recently, the chief end-product of DMPEA, 3,4-dimethoxyphenylacetic acid, has been found in urine from normal and schizophrenic patients19,20, and there were no significant differences between these excretions19. Abnormal methylation in patients with Parkinson's disease might be suggested by urinary excretion of 3,4-dimethoxyphenylacetic acid; further investigation, currently in progress, is necessary to clarify the situation.

Psychotomimetic Indole Compound in the Urine of Schizophrenics and Mentally Defective Patients

BUFOTENIN (Fig. 1), an indole compound first found in the glandular secretion of certain toad species, has been reported to produce psychotic episodes in physically and mentally healthy individuals. Interest has been focused on this compound in the study of biochemical aspects of schizophrenia because of the possible formation of bufotenin in mammalian tissues from the naturally occurring neurohormone serotonin^{2,3}. A bufotenin-like compound has been reported in the urine of schizophrenic patients⁴⁻⁶. Unfortunately, these findings have not been generally accepted because of some defects in the detection methods employed^{7,8}. Others^{7,9-15} have failed to confirm the presence of bufotenin in the urine of schizophrenics as well as non-schizophrenic individuals.

Fig. 1. Chemical structure of serotonin and bufotenin.

One of us⁸ has developed modifications of paper and thin-layer chromatographic methods which are more sensitive and reproducible for detection of small amounts of indoleamines in the urine. Using these methods and also the recently developed gas-liquid chromatographic method of Capella and Horning18, we have confirmed the presence of bufotenin in the urine of four chronic schizo-phrenic patients in rigidly controlled experimental conditions which included amino-acid loading with and with-out a monoamine oxidase inhibitor¹⁷. The psychotic out a monoamine oxidase inhibitor¹⁷. The psychotic symptoms of these patients worsened about 2 weeks after an increase of the urinary bufotenin first appeared and the aggravation of behavioural symptoms continued as long as the increased concentrations of this compound We therefore suggested before 17 that behavioural worsening in schizophrenic patients is partially mediated by greater concentrations of psychotomimetic indoleamines such as bufotenin in the body fluids during the period of exacerbations of their psychotic symptoms.

In our previous investigation we analysed the urine of schizophrenic patients receiving an amino-acid load and/or a monoamine oxidase inhibitor, and so we could not generalize from the biochemical-behavioural relationship about the implication of bufotenin in unprovoked worsening of schizophrenic patients nor its implication in nonschizophrenic patients who may nevertheless exhibit psychotic episodes. The present study was performed on six male, chronic schizophrenics and four male mentally defective patients as non-schizophrenic controls to learn whether or not the urinary excretion of bufotenin is a biochemical characteristic solely of schizophrenia. ages of the mentally defective patients ranged from 59 to 75 yr and their IQ was between 53 and 66 by the Stanford-Binet mental test. The ages of the schizophrenic patients ranged from 33 to 60 yr. Three of these patients belonged to the catatonic group and the other three had been diagnosed as having paranoid schizo-

phrenia. They were placed on a controlled diet which excluded all preformed catecholamines and indoleamines and neither loading with amino-acids nor the administration of a monoamine oxidase inhibitor was carried out. Psychoactive drugs were withheld from all the patients for at least 7 weeks before the initiation of the study and throughout the experimental period. Collections of urine were made every 24 h and the volume and pH were measured. All daily collections were kept frozen at -20° C until analysed, a period of 1–2 weeks.

Urinary indoleamines were examined by a two dimensional thin-layer chromatographic methods. one third of a 24 h volume of urine was concentrated to 50-100 ml. on a rotary evaporator under reduced pressure at 36° C. The free indoleamines were first retained on a sulphonic acid cation resin and then recovered from the resin with 1 normal ammonium hydroxide in 65 per cent ethanol after the acidic and neutral components of the urine had been washed from the resin with 0.1 normal sodium acetate and 50 per cent The urine and the first water wash effluent ethanol. from the resin were collected and hydrolysed at pH 1.0 for 30 min. The conjugated indoleamines were purified from the hydrolysed urine in the same way as for the purification of the free amine fraction. The amounts of purified sample equivalent to 200 mg of creatinine were spotted on a thin-layer of 'Silica gel G' and the chromatograms were developed two dimensionally with isopropanol, ammonia and water (8:1:1) for the first phase and n-butanol, acetic acid and water (12:3:5)for the second. p-Dimethylaminocinnamaldehyde reagent was used for visualization of indole compounds.

Conjugated bufotenin was detected in the urine of all schizophrenic patients as well as of all mentally defective patients examined (Table 1). Furthermore, total amounts of bufotenin excreted in the urine were determined semiquantitatively according to the size and colour intensity of the bufotenin spot appearing on the thin-layer chromatogram and they were estimated to be about the same, less than 1 $\mu g/24$ h for both schizophrenics and the mentally defective patients in our experimental condi-All schizophrenics excreted both free and conjugated bufotenin, whereas in the patients with mental defectiveness, bufotenin was found only in a conjugated form and no free bufotenin was detected except in one patient in our experimental conditions. In this study, the incidence of the patients who excreted free bufotenin was higher in schizophrenics than in the mentally defective We consider, however, that such differences in the incidence resulted from the small number of the patients examined and that there may be no significant differences in the metabolism of bufotenin between schizophrenics and the mentally defective patients in controlled conditions. We did not find any difference in the excretion of conjugated serotonin between these two groups of the patients and so we feel that the mechanism involved in the conjugation processes for both the serotonin and bufotenin is similar.

Table 1. NO. OF PATIENTS EXCRETING BUFOTENIN/TOTAL NUMBER OF PATIENTS EXAMINED

Schlzophrenia Mental deficiency

F. Free bufotenin; C, conjugated bufotenin.

There does seem to be, however, a relationship between free bufotenin and exacerbation of psychotic behaviour. All our schizophrenic patients experienced exacerbations of the psychotic symptoms and they all excreted free bufotenin in association with behavioural worsening. One mental defective who excreted traces of free bufotenin consistently also developed a psychotic reaction with ideas of reference when he was transferred from the open ward to a closed one for this investigation. In contrast, the other

three mental defectives who did not excrete free bufotenin did not exhibit any psychotic episodes. We therefore suggest that there is a positive correlation between free bufotenin and active psychotic symptoms and it seems that free bufotenin plays some part in the aetiology of the psychotic symptoms in mentally ill patients. too few results to draw a conclusion. Only further work can determine whether the presence of free bufotenin in the body fluids is a characteristic of disturbed schizophrenics or if it also occurs in non-schizophrenics who exhibit psychotic episodes.

This investigation was supported in part by a Public Health Service international postdoctoral fellowship to

Cytological Studies of the Pathogenesis of Chronic Lymphatic Leukaemia

WHEN blood lymphocytes from patients with chronic lymphatic leukaemia are examined in Romanovsky stained preparations they show remarkable uniformity in size and appearance and resemble small lymphocytes of healthy individuals. On the other hand, as the basis of other criteria, such as transformation by phytohaemagglutinin¹ or retention on columns of polystyrene beads2, there are differences. To explain these differences it has been proposed that normal and abnormal lymphocytes coexist in the peripheral blood in chronic lymphatic leukaemia²⁻⁴. These studies, however, have not ruled out the possibility that the "abnormal" cell is a type that usually occurs in non-leukaemic subjects, but is found in different proportions in this disease.

We have investigated this possibility by using the supravital staining technique and a divisive procedure (the separation of a large group into smaller ones) for evaluating the results. Although this staining technique has been largely discredited as a means for identifying blood cells, our investigations and those of other workers have shown that mitochondrial content (number of mitochondria per cell), as determined in Janus green B stained supravital preparations, is a useful criterion for

classifying lymphocytes and for comparing lymphocytes from different sites and in various experimental conditions⁶⁻⁹. By employing mitochondrial content, each cell can be quantified and the statistical heterogeneity of the cells collected can be calculated by means of a likelihood ratio test and expressed as the probability, P, of whether the group of cells can be adequately accounted for as a single Gaussian distribution 10 . If P is small, that is below a specified significance level, then the possibility that the data can be described by a single Gaussian distribution is small, and the probability that a heterogeneous—that is, a multiple Gaussian—distribution is present must be considered. Each population can be identified by a mean mitochondrial content and a standard deviation. In this way, it can be determined whether the populations of lymphocytes in patients with chronic lymphatic leukaemia resemble those found in controls. The assumption that frequency distribution curves of the number of mitochondria in a cell would be Gaussian seems justified from histograms, two of which are presented here (Figs. 1Aand B).

The stainability of non-mitochondrial cell components in the supravital staining preparations offered another criterion for comparing lymphocytes. Previously (unpublished data), it was found that lymphocytes showed two distinct colour types when stained with Janus green B. Some cells had a purplish cast (dark cells), while others appeared more or less transparent (light cells). Mitochondria were readily recognized in dark cells because of their distinctive blue green colour; the number of mitochondria in these cells did not differ from that observed in light cells.

Lymphocytes were obtained from four male and two female Caucasians with untreated chronic lymphatic leukaemia. They were 58-74 yr of age and their white blood counts were 22,500-115,900 cells/mm³. A sample

A, Histogram from a non-leukaemic subject (C.P.) which seems to follow a single Gaussian distribution and which shows a single population by computer analysis (P < 0.90), B, Histogram from a non-leukaemic individual (D.W.) which seems to follow a heterogeneous distribution and which shows at least 5 populations by computer analysis (P < 0.01).

Fig. 2. Blood preparations from a patient with chronic lymphatic leukaemia demonstrating a dark and a light lymphocyte. The dark staining structures in these cells are mitochondria. (× 1,200.)

(1 ml.) of blood was obtained from each patient by venipuncture and the preparation of the samples and the counting of the mitochondria (Fig. 2) were done as described previously^{7,11}. A minimum of 100 cells/subject/examination was studied. Re-examinations, at monthly intervals, for at least 5 months were carried out on two patients (D. and P.). Ten male and ten female Caucasian non-leukaemic individuals from the Cancer Detection Clinic Division of the Michigan Cancer Foundation served as controls. They were 44–76 yr of age and their white blood counts were 4,900–9,900 cells/mm³.

Population analyses were carried out with the aid of an IBM 360 computer at the Wayne State University Computing and Data Processing Center, which was programmed to test each set of data for a maximum of five populations. Because of the large number of analyses, a level of significance of 0.01 was considered to be indicative of, and a level of 0.05 to be suggestive of, multiple populations.

The results indicate that 15 per cent of the control specimens contained multiple populations of lymphocytes (P < 0.01), and that an additional 10 per cent could have (P < 0.05) more than one population (Table 1). For leukaemic specimens the figures were 18 and 29 per cent, respectively (Table 2). With few exceptions, the mean mitochondrial content of the various leukaemic populations fell within the range found in healthy subjects (Tables 1, 2 and 3). Significant differences were observed when the mean mitochondrial contents of lymphocyte populations

Figures are either means or means and standard deviations. M, mitochondria/cell.

from different patients were compared (Tables 2 and 3). These differences did not appear to be caused by the disease, for similar variation was also found in controls (Tables 1 and 3). The variation found in chronic lymphatic leukaemia suggests that the leukaemic process was not confined to one population of lymphocytes.

Dark and light cells (Fig. 2) were observed in all preparations (Tables 1 and 2). Various stages in between definitely purple cells and transparent ones were seen, but only those which were definitely purple were scored. In controls, a considerable proportion of lymphocytes were of the dark type (Table 1). In comparison, the proportion of these cells was reduced markedly in patients with chronic lymphatic leukaemia (Table 2).

While the significance and mode of production of dark cells remain unclear, it is known that during the reduction of Janus green B to the leuco form, a violet colour can develop as an intermediate stage¹². Thus it is possible that the dark cells represent lymphocytes incapable of carrying out complete reduction of the dye. Inasmuch as dark and light cells were found within a single population (Tables 1 and 2), we believe that they represent different stages in the life cycle of the lymphocyte. It is interesting to note that the percentage of dark cells found in control and leukaemic specimens resembles the proportion of cells transformed by phytohaemagglutinin which has been reported in the literature¹. Whether this is a coincidence remains to be determined.

We conclude: (a) there are numerous populations of blood lymphocytes in both leukaemic and non-leukaemic individuals; (b) lymphocytes from patients with chronic lymphatic leukaemia are similar to those found in healthy individuals with respect to mitochondrial content; (c) the leukaemic process is not confined to one population of

lymphocyte; and (d) a greater proportion of lymphocytes capable of reducing Janus green B to the leuco form is found in chronic lymphatic leukaemia than in controls. Leukaemic lymphocytes cannot be differentiated from normal lymphocytes on the basis of mitochondrial content as assessed by supravital staining with Janus green B.

We thank Dr Freeman Wilner and Dr Vainutis Vaitkevicius for permission to use their patients for this study. This work was supported by Public Health Service research grants from the US National Cancer Institute and an institutional grant to this institute from the United

Foundation of Greater Detroit.

IMMUNOLOGY

Cellular Distribution in the Bone Marrow after Thymectomy

THYMECTOMY of the newborn animal is known to be followed by a striking deficiency of the lymphocyte population¹⁻³. Data concerning myelopoiesis are not consistent. In some cases, extensive extramedullary haemopoiesis was observed in the spleen of thymectomized mice4. An abnormal persistence and even increase of myeloid tissue in the spleen and lymph nodes of thymectomized opossum embryos has been described. Furthermore, there was an increased ratio of immature to mature erythroblasts, not only in the spleen and lymph nodes, but also in the liver, bone marrow and submucosa of the small intestine. No abnormal extramedullary myelopoiesis has been reported in the thymectomized rats. A quantitative investigation⁶ did not reveal any change in the cell population of the bone marrow of rats after thymectomy, which was performed some weeks after birth, when the weight of the animals was about 70 g. Thymectomy is not likely to be very effective when it is performed so late after birth2.

We describe here a study of the cellular distribution in the bone marrow of rats thymectomized 2 days after birth. Nine Wistar albino rats were thymectomized by the method of Miller'. The absence of macroscopic thymic residues was verified in all cases. The animals were killed by decapitation at about 3, 6 or 12 weeks of age, when the body weight was 50 g, 100 g and 200 g, respectively. Nine normal animals of the same strain and body weight were used as controls; the age/ weight relationships were the same in thymectomized and normal rats. The marrow was removed from the femurs immediately after exsanguination and suspended in autogenous serum: smears were stained by the May-Grünwald-Giemsa method. The differential counts were made on 1,000 cells from each animal. The criteria for the classification of blasts were similar to those of Harris and Burkes: transitional cell forms between lymphocytes and blast cells were included in the blast cells. The term lymphocytes was used for small round cells measuring 7-8µ in diameter, with a very narrow rim of pale blue cytoplasm and a relatively large nucleus composed of an almost homogenous chromatin. Erythroblasts were divided into two groups: all smaller cells with a con-densed nucleus were classified as mature erythroblasts, independent of whether the cytoplasm was basophil, polychromatophil or eosinophil. All immature forms of granulocytes were classified as myelocytes; the differentiated forms, including the stab forms, were grouped in the category of granulocytes. The results are summarized in Table 1.

There seemed to be marked changes in the proportion of the red to the white cells between 3 and 12 weeks; our observations agree well with those of Harris and Burke*. The thymectomized rats did not seem to differ in this respect from the normal animals. They did, however, show a much larger number of blasts at all ages. Another feature common to all thymectomized animals was the presence of a larger proportion of immature erythroblasts to the mature ones.

The latter observation is in agreement with the finding of Miller that thymectomy is followed by arrest of maturation in the erythroblasts of the opossum. The abnormal presence of a large amount of blasts in the bone marrow of the thymectomized rats seems to indicate that the thymus may have an even larger influence in the maturation of the mesenchymal cells than could be inferred from the observations in the thymectomized opossum. The thymus seems to play a part not only in the origin of the lymphocytes and in the maturation of the erythroblasts, but also in the early differentiation of the cells with mesenchymal potencies, at least in the bone marrow.

It seems unlikely that the influence of the thymus is confined to the bone marrow: the stem cells differentiating into blood cells in foci of extramedullary haemopoiesis, as well as other fixed cells with unrestricted mesenchymal potencies, are also likely to be sensitive to the influence of thymus. If this is the case, an explanation might be suggested for the increased phagocytic activity which was shown to occur after thymectomy especially after repeated injections of colloid material^{4,9,10}. It may be that, on account of some lack of differentiation of mesenchymal

PHYSIOLOGY

Susceptibility to Morphine-induced Analgesia in Mice

THE clinical significance of mammalian circadian responses to central nervous system (CNS) drugs has not been adequately established although the implications are impressive 1-11, especially as explanations of unpredictable clinical responses to otherwise thoroughly documented therapeutic agents. This study was designed to determine whether mice, standardized in constant environmental conditions but with alternating 12 h light and dark cycles, would display variations in susceptibility to morphine sulphate along a 24 h scale. Comparisons of susceptibility crests of morphine and other CNS drugs might also provide additional insight into the mechanism of morphine-induced analgesia.

Adult female albino CF-1 mice (Carworth Farms), 26.7 ± 0.2 g body weight, were housed as previously reported¹¹: temperature of $23.3 \pm 1.0^{\circ}$ C; relative humidity of 65 ± 2 per cent; four 40 W incandescent bulbs lit only from 0605 to 1805 h; water and food ad libitum during the fourteen day acclimation period; and dark phase testing with only a photographic safelight as illumination. Preliminary tests indicated that an 8 mg/kg intraperitoneal dose of morphine sulphate most nearly approximated an AD₅₀ (analgesic dose in fifty per cent of tested mice) over a 24 h period. Each mouse was pretested for positive pain response by a modified Haffner test-biting a pinch clamp placed dorsal-ventrally on the base of the tail12. Mice which did not react to the noxious stimulus within 10 sec were rejected.

Beginning at 1500 h and at 3 h intervals over the succeeding 24 h period, groups of eighteen pretested mice were weighed, injected and placed into separate, glass jars. Exactly 20 min after the morphine injection, each mouse was retested. All mice failing to display a positive pain response within 30 sec were considered to be analgesic¹². Responses were transformed into per cent analgesia, relative to the total number of mice injected at that time period. A mean 24 h morphine analgesia response was determined. The methods of Snedecor were used to perform all statistical analyses¹³.

An analysis of variance of the percentage data in Table I revealed that mice are more susceptible to the analgesic

activity of morphine during the dark cycle than during the light cycle of a 24 h period (P < 0.05). A chi-square test of the individual time period data in Table 1 against the mean 24 h morphine response of 49.4+4.4 per cent analgesia indicated that a crest or maximum occurs at 2100 h (P=0.01) and a trough or minimum at 1500 h (P=0.001). The analysis of variance showed a significant difference between the per cent analgesia at each time period within each of the light and dark cycles. This would seem to infer, although not substantiate, the existence of two crests for morphine analgesia within a 24 h period: one crest in each cycle with the greatest reduction in susceptibility (P < 0.05) occurring during the light cycle. Work is in progress to define the exact shape and characteristics of the circadian response pattern for morphine-induced analgesia.

Comparison of the morphine crest at 2100h with crests for other CNS drugs (Table 2) suggests that the peak time for susceptibility to morphine-induced analgesia may have more in common with CNS stimulants than depressants. Of the drugs in Table 2 exhibiting a crest during the dark cycle, all but ethanol possess some central stimulant activity. Ethanol precipitates overt stimulant behaviour brought on by initial depression of the reticular formation, then the cerebral cortex, and not by direct CNS stimulation¹⁴. In large doses lidocaine induces clonic seizures without lethality11 whereas in small doses lidocaine is a depressant producing mild intravenous analgesia14, potentiating pentobarbital sleep and inducing minimal sleep by Flurothyl⁶ is a highly potent CNS stimulant producing major seizures in contrast to the relatively mild stimulation precipitated by the mood-elevating amine oxidase inhibitor, nialamide⁸. Acetylcholine in very large intravenous doses precipitates lethal seizures. Chlordiazepoxide in toxic doses in humans precipitates signs of both central stimulation and depression14.

Morphine is a centrally acting drug with mixed depressant and stimulant activity; analgesia most generally considered to be the result of the depressant activity of morphine on the hypothalamus, thalamus and cerebral cortex14,16,17. In man, the depressant activity of morphine dominates, producing both analgesia and sedation, while in the cat, the stimulant activity (sham rage) is manifested

as well as good analgesia. The mixed activity of morphine is also readily seen in the mouse-good analgesia with stimulation evidenced by the presence of a Straub tail. Morphine exhibits other central stimulant activity: induced hyperthermia18 by stimulation of the hypo $that a mic temperature \ regulating \ centre\ ; increased \ release \ of$ antidiuretic hormone from the pituitary gland14 probably caused by hypothalamic stimulation; cortical stimulation following topical or intracarotid administration19; production of electroencephalic arousal patterns in the hypothalamus and reticular formation 16,17; and lowered threshold to pentylenetetrazol-induced seizures20.

Some CNS stimulants are used clinically as depressants although they produce signs of central stimulation (that is, amphetamines in petit mal epilepsy). Amphetamines also, depending on dosage, may potentiate or antagonize barbiturate depressions. The psychotomimetic drug lysergic acid diethylamide (LSD) and the analeptic methylphenidate induce good analgesia in mice without evidence of depression. Simultaneously with deep, surgical anaesthesia, barbiturates induce good analgesia in dogs but not in either rabbits or guinea-pigs. Nitrous oxide induces fair general anaesthesia but good analgesia. Analgesia therefore does not always correlate well with decreased CNS activity.

Mice also exhibit crests at 2100 h in motor activity, rectal temperature and susceptibility to audiogenic seizures. Concurrence of susceptibility to CNS stimulant drugs with the nocturnal activity pattern of mice provides additional support for the suggestion that morphineinduced analgesia might be more related to central stimulant than depressant activity.

Greater diversity of pharmacological activity is exhibited by the drugs with crests in the light cycle, although central or peripheral depression was the terminal effect of four of the five drugs listed in Table 2 (that is, pentobarbital, methopyrapone, aurothioglucose and ouabain). Nikethamide, a unique analeptic, exhibits primary specificity for the baroreceptors in the carotid and aortic bodies with secondary activity on the medullary respiratory and cardiovascular centres. Reliance on natural daylight rather than a progammed lighting regimen detracts from the significance of the nikethamide data, especially because data were collected on more than one day1. Data collected during periods of reduced susceptibility to morphine were so nearly similar (that is, no precise trough) that no attempt was made to attach significance to the trough data in Table 2.

Neural Release of Brain Serotonin and Body Temperature

FELDBERG^{1,2} has suggested that brain amines are directly involved in the hypothalamic control of body temperature. In cats and dogs serotonin was found to cause a rise in temperature and norepinephrine a fall, whereas in the rabbit3 and sheep4 there is a fall with serotonin and a rise with norepinephrine. Moreover, serotonin antagonizes the normal decrease of temperature of animals under anaesthesia. All these results, however, have been obtained using exogenous amines. We have shown that there is a neurally mediated release of endogenous serotonin in rat brain when the caudal midbrain raphé region is stimulated electrically and we have found that a specific behavioural consequence of such stimulation is a failure of the normal physiological habituation to repetitive sensory stimuli⁵. We have also measured the effect on body temperature of neurally released endogenous serotonin both in awake, unrestrained and in anaesthetized rats.

Male Sprague-Dawley rats (250-350 g) were used. Twelve had chronic electrodes implanted in the midbrain raphé region using a stereotaxic technique. An indifferent electrode was a stainless steel screw embedded in the skull. Both electrodes were connected by 'Teflon' coated wire to female clips and the whole assembly securely attached to the skull by dental cement. Five days or more after the operation rats were electrically stimulated with pulses generated from a Grass S4 stimulator for periods of 0.5 h. The parameters of stimulation were: frequency, 10 pulses/sec; duration, 2 msec; intensity, 1.5-3 V. Observations of the behavioural response to repetitive sensory stimuli were made during this period. Colonic temperature was measured before and after stimulation by means of a telethermometer (Yellow Spring Instrument Some animals were retested after 24 h with reserpine or p-chlorophenylalanine. Rats were decapitated, and brain stems were fixed in 5 per cent glutaraldehyde. Frozen sections were cut and stained for determination of electrode placement.

Table 1. RELATIONSHIP BETWEEN ELECTRODE PLACEMENT AND CHANGE IN BODY TEMPERATURE AFTER 0.5 H ELECTRICAL STIMULATION IN RATS AWAKE AND UNRESTRAINED

No. of animals	Midbrain electrode placement	Mean before	Femperature Mean after stimulation	,
8	Caudal raphé	37.3	38.9	$+1.5 \pm 0.5$
8	Anterior raphé or lateral	37.1	37.3	+0.2+0.2

Sites of electrode placement were the caudal midbrain raphé and adjacent regions. S.D., standard deviation.

The rats with chronic electrodes were electrically stimulated for 0.5 h while awake and unrestrained. Table 1 shows that there was a rise of colonic temperature when the electrode placement was the caudal midbrain raphé. Some animals showing a rise in body temperature were given reserpine (2.5 mg/kg, subcutaneously) or p-chlorophenylalanine (300 mg/kg, intraperitoneally) and restimulated at varying times after the administration of the drugs. It was found that both the drugs reversibly blocked the rise of temperature induced by caudal raphé stimulation. In contrast, certain motor effects of stimulation, a 10 cycles/sec tremor involving whiskers and eyelids, sometimes facial musculature, were not altered by the drugs. As previously reported, stimulation of the midbrain raphé produced a failure of habituation to repetitive sensory stimuli as manifested by a persistence of "startle" responses.

In acute experiments, rats were lightly anaesthetized with chloral hydrate, and stimulated for 1 h with an electrode inserted into the caudal midbrain raphé region. Pairs of these rats were tested in identical conditions of room temperature (23° C) and humidity. Parameters of stimulation were: frequency, 10 pulses/sec; duration, 2 msec; intensity, 6 V. Colonic temperatures were again taken with the telethermometer before and after stimulation. The electrode was present in some rats for 1 h but the animals were not stimulated. After the stimulation, rats were decapitated, brains were dissected out, and the forebrain was removed from the brain stem by a section passing between the rostral border of the superior colliculi and the caudal border of the hypothalamus. The forebrain was analysed for serotonin and 5-hydroxyindoleacetic acid.

Table 2 shows that the stimulated group consistently maintained a higher temperature than control rats (mean difference 1.3° C higher). There was also a significant difference in concentrations of serotonin and 5-hydroxy-indoleacetic acid between the two groups of rats. The group which received raphé stimulation showed a fall in serotonin and a rise in 5-hydroxy-indoleacetic acid.

Table 2. Effect of electrical stimulation of midbrain raphé region on forebrain serotonin, 5-hydroxyindoleacetic acid and body temperature in anaesthetized rats

Ani- Serotonin mals ng/g Change* (No.) ±S.D. (%)	P	ng/g Change* Me	mperature (°C) an ange* P
8 517 + 65		Controls	8 ± 0.4

8 382 ± 62 -26 < 0.001 517 ± 85 +92 < 0.001 -0.5 ± 0.2 < 0.001 *The significance of differences between concentratons in control and stimulated rats was calculated using Student's t test. S.D., Standard deviation.

The results of these experiments show that stimulation of midbrain raphé causes an increase of body temperature (1°-2° C) in the awake unrestrained animal and a reduction in the usual fall in temperature in lightly anaesthetized animals. Indoles in the forebrain were measured in the anaesthetized group and the reduction in fall of temperature with midbrain raphé stimulation is associated with a fall of serotonin and increase of 5-hydroxyindole-acetic acid. These changes in the concentrations of brain indoles after raphé stimulation are in accord with previous results and suggest a release of serotonin. Reserpine and p-chlorophenylalanine reversibly block the rise in tem-

perature with stimulation in awake, unrestrained animals. Both reserpine and p-chlorophenylalanine deplete serotonin in the brain, and reserpine also depletes catecholamines. In contrast, p-chlorophenylalanine does not affect catecholamines appreciably and is in this sense a specific depletor of serotonin'. Together, these facts support the idea that release of serotonin in the brain is linked with the rise of body temperature observed with midbrain stimulation. These data are consistent with Feldberg's hypothesis concerning the role of serotonin in temperature regulation. In particular, there is compatibility between the effects of exogenous and endogenous serotonin both on rise in temperature in awake animals and in opposing the fall of temperature with anaesthesia. Different species were used, however, in the exogenous versus the endogenous experiments.

It is interesting that d-lysergic acid diethylamide (LSD-25) which produces a failure of the normal physiological process of habituation^{8,8} has also been reported to cause an elevation of temperature in rabbits, cats and dogs¹⁰. In man, LSD-25 also increases temperature when it produces its characteristic mental symptoms¹¹. It has been reported previously that LSD-25 causes a fall in temperature in rats¹², but we found that a dose of 200 γ /kg intravenously causes a rise of 1°-2° C in the first 0.5 h

while behavioural effects are maximal. Another related psychotomimetic agent, psilocybin, has also been reported to cause an increase in body temperature¹³. These facts are compatible with the hypothesis that psychotomimetic agents such as LSD-25 may mimic the action of serotonin in brain¹⁴.

Synaptic Structures at Nodes of Ranvier in Spinal Cords of Mice

Bodian and Taylor¹ described presynaptic structures at nodes of Ranvier in the spinal cord of the monkey, and Andrés² reported a similar bouton from a node of Ranvier in the granular layer of the cerebellum of the albino rat.

Fig. 1. Electron micrograph from the dorsal horn of a spinal cord of mouse. A longitudinal section of a myelinated fibre (AX) passes through a node of Ranvier. The nodal axon (NA) bulges out to form a presynaptic bag (PR) which contains mitochondria and synaptic vesicles (V). This nodal bouton forms synaptic contacts with a dendrite (D) which acts as the postsynaptic (PS) structure. Thickening of membranes is indicated by arrows. Scale, 1/a.

I have found two types of synapses at nodes in the central nervous tissue of rabbits³. In the first type, observed in the parietal cortex, the nodal axon gave rise to a process which terminated with a bouton; in the second, described in the reticular formation of the medulla, the nodal axon bulged out to form a synaptic bag.

In the experiments described here, albino mice narcotized with urethane were perfused with a 5 per cent solution of glutaraldehyde buffered with phosphate to pH 7.4 (ref. 4), through a cannula inserted into the abdominal aorta. The cervical region of the spinal cord was excised and thoroughly washed with phosphate buffer (pH 7.4). Small pieces of the cord were post-fixed in a phosphate buffered 2 per cent solution of osmic acid at pH 7.4 at 4° C for 2 h. The material was embedded in 'Maraglas' by the method of Freeman and Spurlock's. Thin sections from the dorsal horn were stained with a lead salt's.

Fig. 1 shows an electron micrograph of a node of Ranvier. The nodal axon bulges out on one side to form a bag which contains synaptic vesicles and mitochondria. The nodal bouton makes synaptic contacts with a dendrite (arrows). At the sites of contact there is thickening of the membranes and accumulation of synaptic vesicles on the presynaptic side. The bulging of nodal axon to form a bouton corresponds to the second type of synapse which I described³ and which was also reported by Bodian and Taylor¹ and Andrés².

Fig. 2 is another example of the synaptic structures at nodes of Ranvier. The nodal axon gives rise to a process or branch which extends for a distance terminating with a bouton. This terminal bouton contains synaptic vesicles and mitochondria. There is no clear evidence that this structure forms synaptic contacts with either the dendrites or the axon terminals surrounding it. Its presynaptic

Fig. 2. Electron micrograph from the dorsal horn of a cord of mouse. The section passes through the longitudinal axis of a myelinated fibre at a node of Ranvier. The nodal axon (NA) gives rise to a branch (B) which terminates with a synaptic bag (SB). Note the presence of mitochondria and synaptic vesicles in the synaptic bag which is surrounded by axon terminals and a dendrite (D). Scale, 1μ .

nature cannot, however, be doubted. The branching of the nodal axon to produce a bouton corresponds to my first type of synapse³ which seems to be the more frequent: synaptic structures of this type were also found in the frontal cortex of rabbit.

Capillary Permeability Effects of Synovial Fluid, AMCHA, E-ACA and Prednisolone Acetate

In the past decade, inhibitors and activators of the fibrinolytic system have undergone extensive study. The chief inhibitors are epsilon-aminocapric acid (E-ACA)¹ and *trans*-aminomethylcyclohexanecarboxylic acid (AMCHA)². This communication compares the effect

of E-ACA, AMCHA and prednisolone acetate, alone and combined with synovial fluid, on capillary permeability measured by the diffusion of systemically injected pontamine blue according to the method of Nitta et al.³. The synovial fluid was obtained with a siliconized syringe from patients with rheumatoid arthritis.

In the first experiment, 0·1 ml. of synovial fluid, 0·1 ml. of saline solution containing 2 mg of AMCHA, 0·1 ml. of synovial fluid containing 2 mg of dissolved AMCHA or 0·1 ml. of saline solution, was injected intracutaneously into the depilated skin of the flanks of nine rats which had previously been injected intravenously with a dose of pontamine blue (60 mg/kg) as a 5 per cent solution.

In the second experiment, 0·1 ml. of synovial fluid, 0·1 ml. of saline solution containing 2 mg of E-ACA, 0·1 ml. of synovial fluid containing 2 mg of E-ACA or 0·1 ml. of saline solution, was injected intracutaneously into each of nine experimental rats.

In the third experiment, a series of nine dye-injected rats received 0·1 ml. of synovial fluid, 0·1 ml. of saline solution containing 0·25 mg of prednisolone acetate, 0·1 ml. of synovial fluid in which was dissolved 0·25 mg of prednisolone acetate or 0·1 ml. of saline solution.

The extent to which dye diffusion occurred was determined as described and the average amounts of the diffused dye are presented in Table 1. Twenty-seven rats were used in this experiment.

In the first experiment, there was a positive effect when AMCHA was injected alone, which was dramatically enhanced when the mixture of AMCHA and synovial

Table 1. PONTAMINE BLUE IN THE SKIN OF RATS INJECTED WITH SYNOVIAL FLUID OF PATIENTS WITH BHEUMATOID ARTHRITIS, AMCHA, E-ACA AND PRED-NISOLONE ACETATE

Injected substances	Pontamine blue (µg) extracted from the skin*				
Synovial fluid	7.6	150-2	20.6		
AMCHA + saline solution	13.0	18.0	15.4		
AMCHA + synovial fluid	42.5	443.7	127.8		
Synovial fluid	8.5	130.0	8.5		
E-ACA + saline solution	15.5	8.0	18.0		
E-ACA + synovial fluid	30.2	261.6	36.0		
Synovial fluid	8.7	19.5	20.6		
Prednisolone acetate + saline solution	23.5	20.1	19-9		
Prednisolone acetate+synovial fluid	3.1	13.7	8-0		

^{*} The data presented in the table are the amount of dye which was obtained by subtracting the control amount using saline solution from the experimen-tal values in each animal.

fluid was injected. Similar though less dramatic results were obtained in the second experiment with E-ACA. The animals treated with prednisolone acetate alone showed little difference from those injected with synovial fluid. When, however, the mixture of prednisolone acetate and synovial fluid was injected, the permeability, as indicated by the dye in the injected area, was less than for either alone.

This series of experiments was prompted by the observation that the synovial fluid of patients suffering from rheumatoid arthritis contains markedly larger amounts of anti-fibrinolysin than the synovial fluid of normal individuals. It was reasoned therefore that the antifibrinolysin is a part of a biological compensatory mechanism designed to offset the inflammatory process. AMCHA and E-ACA were therefore administered intraarticularly in a series of rheumatoid arthritis patients to ascertain this assumption. The results of the clinical studies clearly show that this was indeed the case4.5.

Melmon et al.6 have reported a kinin in the synovial fluid of rheumatoid arthritis and suggested that kinins may contribute to the inflammatory symptom?. In fact, the substance producing permeability (probably kinin) in this experiment seemed to increase in the acute cases. We have recently found that the substance in synovial fluid, derived from incubation with AMCHA or E-ACA, causes contraction of guinea-pig ileum.

If a kinin is a mediator of the inflammatory response, the clinical effects of AMCHA and E-ACA are very hard to understand; however, prednisolone acetate, which does not produce the substance which causes the enhanced permeability, is supported by our observation.

Objections to the role of bradykinin as a mediator of the inflammatory response have been raised by Miles, who points out that bradykinin has not been shown to produce the histological picture of capillary damage known to predominate in the late phase of inflammation, and by Phelps et al.8, who suggested that bradykinin is not a mediator of the acute inflammatory response induced by injection of urate crystals into canine joints.

The relationship between the substance in synovial fluid, derived from AMCHA or E-ACA incubated in synovial fluid, and bradykinin remains a matter for conjecture.

Anaemia, Thrombocytopenia and Reduced Platelet Adhesiveness in Rats fed Bracken Fern, and Protective Effects of Batyl Alcohol

In cattle, the bracken fern (Pteridium aquilinum) produces haematological changes which are characteristic of an aplastic anaemia1. In the horse and rat the syndrome is one of thiamine deficiency caused by a thiaminase enzyme in the bracken²⁻⁴.

Following reports that D-batyl alcohol (D-α-octadecylglycerol ether) protected mice from total body X-irradiation⁵ and patients from irradiation leukopenia⁶, Evans et al.7 administered this substance to three of four bullocks with experimentally induced bracken poisoning and observed a rapid improvement in condition and a return towards normal values of both platelet and leucocyte counts. Recently, Evans and Mason⁸ reported that the prolonged feeding of bracken to rats caused multiple malignant adenocarcinoma of the intestinal mucosa.

In July and August of 1966, approximately 425 lb of bracken was collected in Southwestern Ontario and oven-dried at 40° C until the weight was reduced to about one-third. The dried bracken was then ground and mixed with ground Purina Lab Chow pellets sufficient to restore the bracken to its original weight. A control group of rats was fed Purina Lab Chow in pellet form. All food was available ad libitum, as was the drinking water, all of which contained thiamine hydrochloride (10 mg per litre).

Male, Long-Evans hooded rats (230-280 g) were randomly assigned to one of four groups; forty-four rats (group A) were fed the bracken diet, forty-four rats (group B) received the bracken diet to which had been

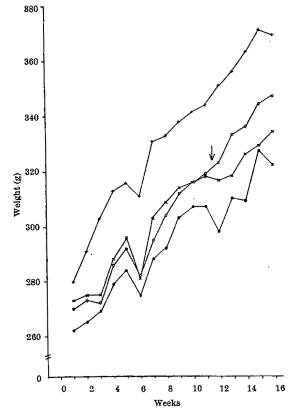

Fig. 1. Growth curves are shown for rats fed a diet consisting of 38 per cent dried bracken fern, with and without added batyl alcohol (75 mg/kg of food). All rats received thiamine in the drinking water (10 mg/l). The rats which were fed bracken gained weight poorly, as compared with rats fed the standard colony diet, regardless of the inclusion of batyl alcohol. — Fed bracken; ×, fed bracken with batyl alcohol; O, fed bracken as far as arrow, then normal diet; +, normal diet.

added baty alcohol (75 mg/kg of food), twenty-four rats (group C) were fed the same bracken-plus-batyl alcohol diet for eleven weeks and were then changed to the standard colony diet, and fifty rats (group D) were given the standard colony diet throughout the experiment. The rats were caged individually and were weighed weekly.

Each week some rats from each group were anaesthetized with sodium pentobarbital and 5 ml. of blood was drawn from the posterior vena cava into siliconized glass syringes containing 7 mg of disodium EDTA in 0.2 ml. of saline. Red blood cells and white blood cells were counted in a Coulter electronic counter. Platelets were counted before and after the passage of blood through a 5 g column of glass beads (0.5 mm diameter). The percentage of platelets remaining in the column was calculated (percentage adhesiveness). Counts were done with Spencer-Brightline haemocytometer chambers using Wright's modification of Reese-Ecker's diluting fluid.

Haemoglobin concentration was measured spectrophotometrically using Hycel, Inc. (Houston, Texas), reagents and the mean corpuscular haemoglobin (MCH) was calculated.

The growth curves (mean weekly weights) are shown in Fig. 1. The data suggest the following conclusions: the rats fed the standard diet gain weight at the fastest rate and reach the highest mean weight at the end of sixteen weeks; the inclusion of batyl alcohol in the bracken does not improve appreciably the rate of weight gain; and there is a rapid improvement in weight gain in the group which was transferred from brackenplus-batyl alcohol to the standard diet.

The results of the blood studies are shown in Table 1. There were no statistically significant differences in red cell counts between any of the groups. White cell counts were depressed in those rats which were fed bracken with or without added batyl alcohol (groups A and B), but the differences were not statistically significant. Platelet counts were significantly (Ps < 0.01) depressed in the rats which were fed bracken regardless of the inclusion of batyl alcohol (groups A and B). Removal from the bracken diet restored the platelet count to above normal (group O). These differences were statistically significant by analysis of variance (P < 0.01). Platelet adhesiveness was drastically reduced in the bracken-fed rats (group A), noticeably improved when batyl alcohol was included in the bracken diet (group B) and restored to near normal if the standard food was substituted for bracken (group C). Again, these differences were statistically significant by analysis of variance (P < 0.01). The haematocrit value of the control group (D) which received the standard diet was significantly greater than that of any of the other groups (Ps < 0.02-0.05), indicating a microcytic anaemia in the bracken-fed rats which was not favourably influenced by the inclusion of batyl alcohol in the diet. The mean corpuscular haemoglobin of the rats which were fed bracken alone (group A) was significantly lower than that of any of the other groups (Ps < 0.02 to 0.05).

These results suggest that the rats which were fed bracken developed microcytic, hypochromic, normocythaemic anaemia with mild leucopenia and more marked thrombocytopenia. The adhesiveness of platelets to glass was drastically reduced: The inclusion of batyl alcohol in the diet did not influence favourably the leucopenia, the thrombocytopenia or the size of the red cells, but it did

restore the mean corpuscular haemoglobin to normal and improved the adhesiveness of the platelets.

To date (July 12, 1967) two rats have shown evidence of malignancy. One of these was from group C, which was removed from the bracken diet; the other was from group B, which was treated with batyl alcohol. Both rats had large, purplish tumours about one inch in diameter in the area of the small bowel, and enlargement of the mesenteric lymph nodes and spleen. Histological sections are being prepared. All of the rats have now been on the standard colony diet for ten weeks, owing to the depletion of the bracken diet.

We thank Mrs I. Francey and Miss J. Stewart for their able technical assistance. This work was supported by a grant to R. B. P. from the Medical Research Council of Canada, and a grant to the authors from the National Cancer Institute of Canada.

Cell Regeneration in **Protein Deficiency**

LESIONS of organs with a high protein turnover are characteristic of kwashiorkor in humans1. These lesions have been reproduced in rhesus monkeys by feeding them protein deficient diets2. On the basis of a study of the cell population kinetics of the mucosa of the small intestine in this primate, it has been suggested that a retardation of cellular proliferation is characteristic of protein deficiency3. In this communication, we describe preliminary observations on the influence of protein deficiency on cell population kinetics in regenerating livers of rats after partial

Twenty-six male albino Wistar rats, 120-150 g, were divided into two equal groups; one group was fed a protein deficient diet containing 1 per cent casein given freely for 5-6 weeks; the other, control group, was fed a diet containing adequate protein (16 per cent casein) for an equal period. Each animal in the second group was pair-fed with a corresponding animal in the protein deficient group. Both groups received other essential nutrients in adequate quantities.

All animals were subjected to partial hepatectomy by the method of Higgins and Anderson. Hepatectomy was always performed at fixed hours in the morning. overcome the differences caused by diurnal variation in

mitotic activity, animals from both groups were killed at the same time of the day. The rate of cellular regeneration was assessed by making mitotic counts of liver sections of animals, biopsied or autopsied 24 and 28 h after hepatectomy. The rate of mitosis had begun to increase by 24 h after hepatectomy in both the groups, and so colchicine (0.75 mg/kg) was administered intraperitoneally at this time to five animals in each group and the animals were killed 4 h later. Colchicine is known to arrest mitosis in the metaphase, and so the cumulative mitotic activity was measured in this way for both groups during the 4 h interval. DNA synthesis was assessed by estimation of labelling index 1.5-2 h after the administration of 3Hthymidine (50 μ c./100 g of body weight) intraperitoneally 22 h after partial hepatectomy. (Labelling index: number of hepatic parenchymal cell nuclei which were labelled in each 1,000 cells.) This time interval was chosen because it is known that in normal rats labelling is greatest 20-22 h after partial hepatectomy. The labelling index in some animals from both groups was also determined 6 h after the administration of thymidine. The difference between the labelling indices 2 and 6 h after thymidine would give an idea of the rate at which cells were dividing during the 4 h interval. A total of 2,000 hepatocytes was counted for the estimation of mitotic and labelling indices in each case. (Mitotic index: number of hepatic parenchymal cells undergoing mitosis in each 1,000 cells.) The number of animals used in each group is shown in Table 1 and the results are shown in Table 2.

The significant rise in the labelling index in the control group between 24 and 28 h after partial hepatectomy as

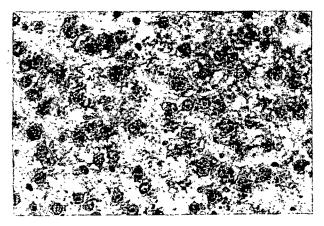

Fig. 1. Autoradiograph counterstained with haematoxylin and eosin 24 h after partial hepatectomy. 3 H-thymidine was administered 2 h before death. Control rat (× c. 275).

compared with the protein deficient group which shows no significant change during this interval indicates poor cellular proliferation in protein deficiency. This feature is revealed independently by comparing the mitotic indices 24 and 28 h after partial hepatectomy in animals given colchicine. Striking differences are found in the rates of accumulation of mitotic figures during this 4 h period between the two groups again emphasizing the inability of the protein deficient animals to keep pace with the control group in cellular proliferative response after partial hepatectomy.

The high mitotic index 28 h after hepatectomy in the protein deficient group is probably the result of slowing down the cell division. The hepatocytes in these animals seem to stay in mitosis for longer than in the controls, thus giving a relatively high mitotic index. At first sight the higher labelling index at 24 h in the protein deficient group may suggest an enhanced cell turnover in this group. Both the mitotic and labelling indices of animals given colchicine, however, suggest a marked depression of the rate of cellular proliferation in protein deficiency. The higher labelling index in the protein deficient group might be explained on the basis of a prolongation of the DNA synthetic phase which in turn would lead to an expansion of the number of cells capable of taking up thymidine and thus of being labelled3.

α_2 -Macroglobulin as Progressive Antithrombin

For several years we have been interested in the antiprotease activity of human α_e -macroglobulin $(\alpha_2 M)^{1-\delta}$. The antitrypsin and antiplasmin effect of this macroglobulin has already been studied 8-8. During work on the antiplasmin activity of a2M, using a very sensitive fibrinolytic system¹⁰, we found that the interaction between α2M and this protease required several minutes for completion. a2M has a molecular affinity for plasminogen and

fractions obtained by gel filtration on 'Sephadex G-200' are usually contaminated by this proenzyme. Preparations of a2M suitable for studying anti-protease activity should not be contaminated with plasminogen because such α₂M shows less apparent anti-protease activity than an uncontaminated preparation. It is necessary to detect such contamination, for α_2M inactivates plasmin within a few minutes. α_2M should be isolated from plasma because in the serum it has already adsorbed thrombin and

eventually will even take up plasmin. We prepared $\alpha_2 M$ by a technique involving adsorption of contaminating plasminogen by bentonite, but we used less bentonite4 than the original technique. We found that the interaction between a2M and plasmin needed a reaction time of several minutes, and so considered that $\alpha_2 M$ might have the properties of a progressive anti-thrombin. $\alpha_2 M$ proved to be a potent progressive antithrombin (Fig. 1). Human $\alpha_2 M$ inhibits human, bovine, equine and chicken thrombin. The affinity seems to differ from one species to another. Whereas $\alpha_2 M$ inhibits clotting activity of thrombin, it does not inhibit esterase activity, thus showing a behaviour very similar to that with trypsin or plasmin4,7,9.

α₂M has no heparin co-factor activity; using purified human thrombin and fibrinogen we did not observe any immediate antithrombin activity when varying amounts of heparin were added to $\alpha_2 M$. To investigate this lack we submitted human serum to preparative ultracentrifugation. Progressive antithrombin activity was enriched at the bottom of the tube and heparin co-factor activity remained in the top layer.

We also prepared specific antibodies to human α2M from 80 ml. of rabbit anti-a₂M. The concentrated solution of the isolated antibody was added drop-wise to human serum until no more precipitate appeared. After removal of the precipitate progressive antithrombin and heparin co-factor activity were tested in the supernatant: the progressive antithrombin activity dropped (about 30 per cent) whereas co-factor activity was slightly greater than in the untreated material.

Methylamine (0.25 molar) splits $\alpha_2 M$ at pH 7.2, as shown by starch gel electrophoresis. This material shows neither antitrypsin, antiplasmin^{4,5} nor antithrombin activity, which can be restored by dialysis. The dialysed material, however, shows the characteristic double (or

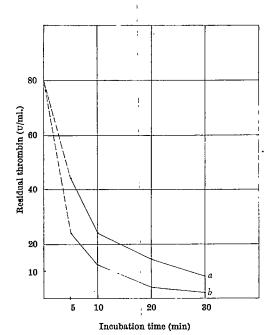

Fig. 1. Antithrombin activity of a_2M . a_1 , a_2M 0.2 per cent; b_1 , serum diluted 1:1.

Fig. 2. Starch gel electrophoresis (microtechnique). (1) Serum; (2) a_2M ; (3) a_2M and thrombin (200 v/ml.). The higher the thrombin concentration the more important is the splitting of the a_2M band.

triple) band of a2M treated with methylamine. Serum containing methylamine at neutral pH to a final concentration of 0.25 molar loses its progressive antithrombin activity—and the activity is only poorly restored by dialysis in the case of whole serum. We have thus found that three different methods—preparative ultracentrifugation of whole serum, an immunochemical method and use of methylamine as a specific inhibitor of α₂M—gave evidence that $\alpha_2 M$ is a natural progressive antithrombin. Heparin co-factor activity seems to correspond to another molecular support.

Cyanopsin, a Visual Pigment of Retinal Origin

In 1953, Wald¹ reported in vitro synthesis of a new photosensitive pigment. This was made by combining the opsin obtained from extracts of chicken iodopsin2 with 11-cis retinene, in place of the native 11-cis retinene,. The pigment thus formed absorbed maximally at 620 nm instead of the native 562 nm, and was named cyanopsin. It had a number of properties which made it a good candidate for a visual pigment, although it had not been extracted directly from any retina and could not therefore be associated convincingly with the visual system of any animal. Such a pigment has yet to be extracted from a retina; but, in addition to discovering whether a pigment like cyanopsin exists in nature, and, in particular, in cones, it would be satisfying to observe whether there exists a natural iodopsin in situ to which the 620 pigment is related by a simple change of prosthetic group.

Speculation that the synthetic pigment cyanopsin would turn out to be a cone pigment has received some support from microinvestigations3,4; a spectrophotometric photosensitive pigment of λ_{max} of approximately 620 nm was found among the three goldfish cone pigments reported. The retinal changes accompanying metamorphosis of the frog, Rana pipiens, however, would seem to provide a better biological basis on which these matters might be tested, for at meta-morphosis the frog performs Wald's experiment in reverse. In this species, the retina changes at metamorphosis from that of the tadpole, which contained only retinene, to that of the adult, which contains only retinene. Extraction studies have already shown that metamorphosis is accompanied by a conversion from porphyropsin to rhodopsin (presumably in the rods) in the bullfrog, R. catesbeiana^{5,6}. This report describes the pigment content of retinal cones of R. pipiens before and after metamorphosis and compares these with pigments of turtle cones and the pigment pair iodopsincyanopsin Wald has investigated. The observations were made by single cell microspectrophotometry.

Eyes were removed from freshly guillotined 5 cm tadpoles without legs, previously dark adapted for more than 1 h, and, similarly, from adult frogs and turtles. Retinas were removed in 0.7 per cent saline and 1 mm² pieces were further reduced in size on a cover slip and closed with another cover slip for microscopy. These preparations provide

cells which are viewed side on. A microbeam measuring $1\mu \times 4\mu$ was passed through either cone or rod outer segments in the microspectrophotometer for the measurements described. The beam was polarized with its electric vector perpendicular to the long axis of the outer segment. All dissection and manipulations before the actual measurement of absorption spectra were carried out in infrared illumination with the aid of infrared image converters, to prevent bleaching of photosensitive pigments before measurement. Spectra of each cell were scanned automatically from 750 nm to 400 nm. The scanning time and band width of the instrument were previously adjusted to provide an acceptable signal to noise ratio without destroying an unacceptable amount of the visual pigment with the measuring photons. Although this objective becomes very difficult to achieve in the red region of the spectrum because of poorer photocathode quantum efficiency, we have used a photomultiplier of exceptional red response in our microspectrophotometer with satisfactory results.

Figs. 1 and 2 show that the microphotometric recordings of rods from tadpole and frog confirm the demonstration by extraction that porphyropsin is replaced by rhodopsin after metamorphosis. The λ_{max} of the absorption spectrum of a tadpole cone shown in Fig. 3 matches

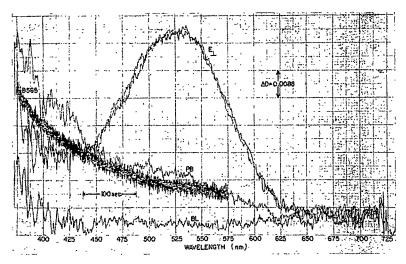

Fig. 1. Tadpole rod outer segment. E_1 , Two successive spectra scanned from red to violet. B 565, Kinetic curve of bleaching produced by steady illumination at 565 nm. closely that of the longwave goldfish cone as well as Wald's curve for cyanopsin. The absorption spectrum of adult frog cones (Fig. 4) differs slightly from that of chicken iodopsin in that its maximum absorption occurs at about 570 nm instead of at 562 nm. We have found only the 570 nm pigment in all oil drop containing frog cones, and, similarly, only the 620 nm pigment for the tadpole. In collaborative experiments with Dr A. M. Granda (unpublished work), we have found the cones of the freshwater tortoise, *Pseudemys scripta*, to contain the 620 nm pigment while the cones of the seawater turtle, *Chelonia mydas*, contain a 565 nm pigment. (The former uses retinene₂, the latter retinene₁, as the prosthetic group.)

Thus a pigment spectroscopically indistinguishable from cyanopsin has now been found directly in three families of animal—fish, amphibian and reptile—known to use retinene, as a visual pigment prosthetic group. Furthermore, it has been found in two of these that the comparable retinene, based cone pigment is spectroscopically close to or identical with iodopsin. Our results are not therefore inconsistent with Wald's speculation that a pigment like or identical to cyanopsin occurs in nature, that it is a cone pigment, and that the opsin from which it is derived may combine with retinene, to

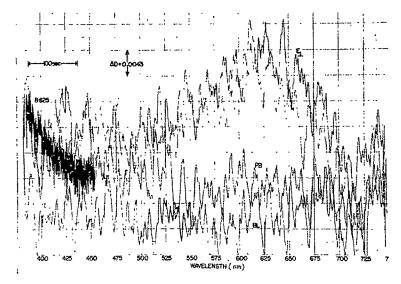

Fig. 3. Outer segment of tadpole principal cone.

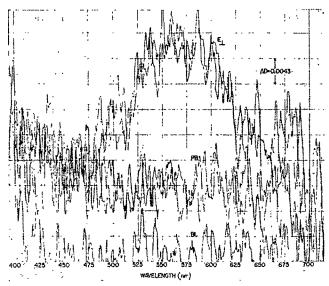

Fig. 4. Outer segment of frog principal cone.

form a functional cone pigment not dissimilar from iodopsin.

Difference in Swelling and Opacity Formation between Young and Old Lenses

THE present theory of cataract formation in young galactose-fed animals and in young diabetic animals suggests that accumulation of dulcitol or sorbitol in the lens causes

it to swell and that this swelling leads to metabolic upset and opacity formation1,2. Patterson and Bunting³, however, have suggested that another metabolite, the nature of which is still unknown, contributes to swelling and opacity formation in the young lens of the galactose-fed rat. This idea is based on their finding that swelling is greater and opacity formation both quicker and more complete in the young rat lens than in the mature rat lens, although dulcitol accumulation is the same in both. It is true that the presence of another metabolite of galactose, besides dulcitol, could explain these observations, but it is also possible that differences between young and mature lenses could be caused by a physical difference in the elasticity of the lens capsule and fibre membranes rather than to any chemical difference.

To test whether elasticity was involved, lenses from rats of different ages have been immersed in distilled water and their change in weight, final wet weight

to dry weight ratio and protein loss have been measured. Swelling of the lens in the galactose-fed rat is brought about by the accumulation of one or more osmotically active substances within the lens. Swelling of the lens immersed in distilled water is brought about by reduction of osmotic pressure in the medium outside the lens: no metabolic processes are likely to be involved.

Table I shows that there is an even greater difference in swelling and degree of hydration between the young lens and the mature lens immersed in distilled water than there is between the lens of the young and mature galactose-fed rat. In one experiment, the increase of volume and of surface area of the lens was calculated, on the assumption that the rat lens is a sphere. The young lenses showed a 70 per cent increase in volume and a 44 per cent increase in surface area, while the lenses of the mature rat increased 46 per cent in volume and 29 per cent in surface area.

Exposure of the lens to distilled water is a drastic procedure and it was interesting to watch the progressive changes that took place in the two types of lens. In both, nearly all the uptake of water and increase in weight took place in the first 10–30 min. The suture lines became easily visible and over the next 6–8 h the centre of both young and mature lenses became progressively cloudy. By the next morning the two types of lens were noticeably different. The young lens had a dense white nucleus while the mature lens remained cloudy blue grey.

75 250 300	27·8 34·1 39·1	7·5 12·8 15·8	3·7 2·66 2·47				

* The numbers in parentheses are the numbers of lenses.

The ratio of wet weight to dry weight of the lens falls from 2·62-2·34 with increasing age in the normal rat*. The lenses were removed by equatorial incision of the eye in situ, cleansed of tissue with a camel hair brush, weighed on a torsion balance and at once immersed in 1-2 ml. of distilled water for 20 h at 20° C.

Table 2. ESCAPE OF PROTEIN FROM RAT LENS OF DIFFERENT AGES INTO DISTILLED WATER

Weight lens mg	$\mu \mathrm{g/lens}$	Protein diffused into n $\mu g/mg$ wet weight (normal lens)	nedium µg/mg dry weight (swollen lens)
23 (2)	1.580	69	
19 (3)	1.140	60	194
20 (20)	890	44	
22 (2)	1,200	$\bar{54}$	266
21 (3)	1,090	52	
45 (4)	820	18	46
44 (4)	1.050	24	63

Conditions are as described in Table 1. The numbers in parentheses are the numbers of lenses. Protein was estimated by the bluret method of Robinson

Sippel⁴ examined the protein content of the lens in young galactose-fed rats and found that it decreased at about the time that the dense nuclear opacity appeared. This decrease coincided with appearance of protein in the fluids of the eye, probably indicating an increase in permeability of lens fibre membranes and capsule which are normally almost impermeable to lens proteins. Table 2 shows that protein escapes from lenses immersed in distilled water and that this is greater from the young than from the mature lens. The dry weight of the swollen lens is almost entirely protein and the loss from the young lens represents about 20 per cent and that from the mature lens about 5 per cent of the total protein. It is possible that the loss of protein is connected with formation of dense nuclear opacity in the young lens. Waley⁵ noted that a macerated lens remained transparent but that addition of fluid caused turbidity to develop. Charlton and van Heyningen⁷ have evidence that proteins of small molecular size may have been lost from the senile cataractous lens by leakage.

In swelling, in opacity formation and in capsular permeability the behaviour of the young and of the mature lens exposed to distilled water parallels the behaviour in vivo of the lenses of young and mature galactose-fed rats. It seems probable that the cause of the difference is the same in both cases and the simplest explanation of the difference in swelling is that the capsule and fibre membranes of the young lens are more elastic and more permeable than those of the mature lens. It is generally agreed that the human lens becomes less elastic with age as presbyopia develops.

Incorporation of Sulphur-35 into the Subcommissural Organ and Reissner's Fibre

THE subcommissural organ (SCO) is a specialized area of the ependymal border below the commissura posterior and it occurs in the brain of all vertebrates. In most species the products of apical secretion from the SCO may pass, as does Reissner's fibre, through the ventricles of the brain and the central canal to the posterior end of the spinal cord^{1,2}. The function of the *SCO* is not yet known.

Histoautoradiographic investigations after the injection of **S-cystine (1.2-4.8 µc./body weight, partly repeated) have shown that 35S-incorporation of sulphur-35 into the SCO and Reissner's fibre in the carp (Cyprinus carpio L.) is greater than in most other organs (Figs. 1 and 2).

1. RELATIVE CONCENTRATIONS OF SULPHUR-35 IN THE BRAIN AND OTHER ORGANS OF CARP AFFER SEVERAL INCUBATION PREIODS Table 1.

Time of incubation (days)	Injected ac- tivity/g of body weight (μc.)	sco	RF	NS	σ	L	G	I
$^{2}_{14}$	4·75 4 × 2·5	5·5 2·6	6·4 5·7	3·4 2·3	2·2 2·0	4.0	6.8	8.3

RF, Reissner's fibre; NS, neurosecretory areas in the brain; C, cerebellum; L, liver; G, goblet cells of the midgut; I,β cells in the islets of Langerhans.

The relative concentrations of sulphur-35 in the different tissues were determined photometrically (Table 1) and the only structures with a greater cystine content than the SCO and Reissner's fibre were the goblet cells of the midgut and the islets of Langerhans. When the spinal cords of carp (weight, 530-750 g; brain and spinal cord, 15-20 cm) were fixed and investigated autoradiographically several days after the injections of sulphur-35 the activity in Reissner's fibre was found to have moved daily 2-3 per cent of its total length, giving an absolute measurement of about 0.5 cm/day. Thus it takes about 40 days for substances from the fibre to pass through the central canal of the spinal cord.

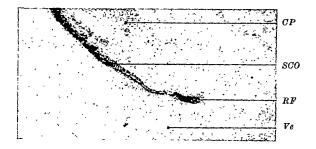

Fig. 1. Autoradiograph of unstained longitudinal section through the SCO and Reissner's fibre. (\times 50.) CP, Commissura posterior; SCO, subcommissural organ; RF, Reissner's fibre; Ve, third ventricle.

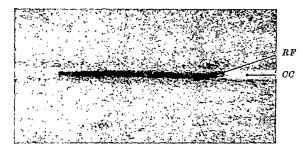

Fig. 2. Autoradiograph of a longitudinal section through the spinal cord with the central duct and Reissner's fibre. (\times 50.) RF, Reissner's fibre; CC, central canal.

These results show that there is intensive metabolism of sulphur containing substances in the SCO, and these must include the complex mucopolysaccharide-protein which has been demonstrated in Reissner's fibre system²⁻⁴.

BIOCHEMISTRY

Pesticide-induced Enzyme Breakdown of Steroids in Birds

WIDESPREAD and severe decreases in the population of several species of birds of prey have been noted in both North America and Europe during the past decade1-4. It has been thought that these decreases are caused by pesticides, but concentrations of pesticide residues found are often low compared with a toxic dose5. evidence from laboratory studies that gross blockage of the reproductive system does not occur except at concentrations approaching toxic doses^{6,7}. More subtle effects on the breeding cycle caused by changes in hormonal concentrations and neurotoxic effects may be important. The effects of low doses of DDT (1,1,1-trichloro-2,2di(4-chlorophenyl)ethane) and dieldrin (1,2,3,4,10,10-hexachloro-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydro-exo-1,4-endo-5,8-dimethanonaphthalene) on the metabolism of two steroid hormones, testosterone and progesterone, have been examined. It has been shown in several mammalian species that a wide variety of organo-chloride pesticides induce increased concentrations of hepatic enzymes which are capable of hydroxylating the natural steroid hormones^{8,8}. Birds were used in this work and the possibility of additive or synergistic effects of DDT and dieldrin was examined.

White King pigeons, which were about 1 yr old and weighed about 600 g, were used, females for the progesterone experiments and males for the testosterone experiments. DDT (10 p.p.m.) and/or dieldrin (2 p.p.m.) were fed to the pigeons for a week. The amounts ingested were approximately 5 mg of DDT and 1 mg of dieldrin. All pigeons were killed 4 days after the end of the pesticide treatment. The enzyme extraction procedure was essentially that of Conney and Klutch¹⁰. The liver was homogenized in cold 0·25 molar sucrose; nuclei, mitochondria and cell debris were removed by centrifugation at 9,000g for 15 min at 4° C. The microsomal fraction was obtained by centrifuging for 1 h at 105,000g at 4° C and the pellet was washed with 0·25 molar sucrose; 300 mg was then resuspended in 3 ml. of KH₂PO₄-K₂HPO₄ buffer (pH 7·4)

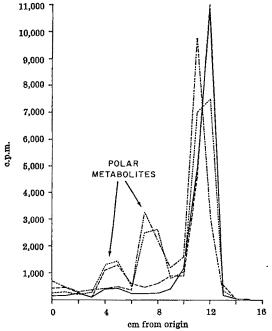

Fig. 1. Chromatographic separation of testosterone and its metabolites. The large peak is unaltered testosterone. Experimental conditions given in text. ..., DDT+dleidrin; ..., ..., dieldrin; ..., DDT; ..., DDT;

by mild sonification for 5 sec. To this were added 500 mumoles of steroid (progesterone-4-14C, 36·1 mc./mmole or testosterone-4-14C, 29-2 mc./mmole), 3 mg of TPN (in 0.75 ml. of 0.05 mole tris), 14 mg of glucose-6-phosphate (in 0.5 ml. of 0.05 molar tris), 0.25 ml. of 0.05 molar MgCl₂ and 5 Kornberg units of glucose-6-phosphate dehydrogenase. The mixture was incubated at 40° C for 30 min with a slow stream of 95 per cent oxygen and 5 per cent carbon dioxide passing through the incubation flask. The steroids were extracted with 30 ml. of dichloromethane, evaporated to dryness under nitrogen and then dissolved in 1 ml. of methanol. The steroids were then separated by paper chromatography using the upper layer of cyclohexane, methanol and water (10:10:1) for testosterone and its metabolites, and decalin, nitromethane and methanol (2:1:1) for progesterone and its metabolites. Each chromatogram was cut into sections I cm long and each section was counted in a liquid scintillation counter using Bray's solution¹¹. Plots of c.p.m. against distance from the origin for the two systems are shown in Figs. 1 and 2. The amounts of metabolites formed were calculated from the areas under the curves, and are summarized in Table 1.

Table 1. INCREASE OF STEROID METABOLISM IN PIGEONS TREATED WITH DDT AND DIELDRIN

a	Amount of polar in mu	netabolites forme moles
_	Testosterone	Progesterone
Control DDT Dieldrin DDT+dieldrin	$28.7 \pm 4.7 (8)$ $75.4 \pm 18.0 (6)$ $111.4 \pm 12.7 (6)$ $168.2 \pm 9.9 (4)$	30·1 ± 8·4 (8) 78·3 ± 8·4 (6) 90·3 ± 6·1 (6) 155·4 ± 17·8 (4)

The mean and the standard deviation are given with the number of birds shown in parentheses. In all cases 500 m μ moles of labelled substrate was present, incubation time was 30 mln, and weight of microsomal fraction used was 300 mg.

The chromatographic patterns of both testosterone (Fig. 1) and progesterone (Fig. 2) after DDT and dieldrin stimulation show that the metabolites formed are different. The data suggest that different enzyme systems are induced by the two pesticides. Pretreatment of pigeons with both DDT and dieldrin gives rise to a curve with two metabolite peaks. The sizes of the peaks are similar to those produced by the individual pesticides alone. Thus it appears that the effects of the two pesticides are additive but not synergistic.

The experiments demonstrate that relatively small amounts of DDT and dieldrin can induce increased rates of metabolism of steroids by induction of hepatic enzymes.

The relationship of elevated steroid metabolism in the liver to the concentrations of circulating steroids has not been established. DDT has been used to decrease concentrations of cortisol in patients suffering from Cushing's syndrome¹² and to perform "chemical adrenalectomy" in the treatment of carcinoma of the breast and prostate13. At least in these abnormal conditions it is possible to alter steroid concentrations by the use of chlorinated hydrocarbons. The effect of induced enzyme metabolism has been demonstrated by in vivo experiments on the metabolism of circulating phenobarbital in the rat. The duration of barbital hypnosis was reduced from 81 min in the control animals to 39 min in rats given 2 mg/kg of DDT intraperitoneally 48 h earlier⁸. In this case, a relatively small dose of insecticide had a profound influence on the effects of a circulating material. There is evidence to suggest that the same enzyme systems are responsible for steroid and barbital metabolism9. It is possible that the feed-back mechanism through the hypothalamus and the anterior pituitary might be able to maintain the normal concentrations of steroids. Radcliffe's14 observation of the decrease in weight in recent years of the eggshell of some birds of prey could be explained by increased metabolism of oestrogen induced by hepatic enzymes. Many studies indicate that overcrowding imposes a stress on animals and causes reduced secretion of gonadotrophic hormones which affects the reproductive organs^{15,16}. If normal regulation of populations depends on a subtle balance of hormone concentrations and related feed-back mechanisms associated with population density, it would not be surprising to find that agents affecting this balance cause declining populations.

Three Lactic Dehydrogenase Isoenzyme Systems in Pig Spermatozoa and the Polymorphism of Sub-units controlled by a Third Locus C

ELECTROPHORESIS usually reveals five lactic dehydrogenase (LDH) isoenzymes in vertebrate tissues. Each isoenzyme is considered to be a tetramer, usually composed of two sub-units, polypeptide monomers A (LDH₅) and B (LDH₁). Genetic evidence¹⁻³ indicates that synthesis of the polypeptides is controlled by two loci, A and B. In testis and spermatozoa from different animals, with the exception of pigs4,5, six to eight fractions were

The extra bands were named x-bands. discovered. Zinkham and Blanco⁶ found that the LDH_x-band in pigeon testis is polymorphic, and concluded that this is controlled by a third locus C. Ressler et al. suggested that LDHx-band in human spermatozoa is formed from A and B sub-units and some other compound. Zinkham et al.4 and Goldberg5 found that in vitro sub-units of LDH_x can produce mixed forms with sub-units A and B.

In pig spermatozoa, we have found evidence for a third locus C with two different alleles. The polymorphic sub-units C and C' form in vivo a new LDH isoenzyme system with sub-units A and B. Furthermore, a third system, which probably does not involve A, B and C sub-units, was found.

Pig spermatozoa from the tail of the epididymis⁸ were washed with an isotonic glucose solution or 0.9 per cent sodium chloride, and centrifuged (3,000-4,000 r.p.m.) for 15 min. Redistilled water or tris citrate buffer (pH 7.0) $(\mu = 0.05)$ was added in a volume half that of the spermatozoa, and one part was homogenized immediately in a Potter-Elvehjem homogenizer at 0° C and another part was frozen (-20° C) and thawed once. Both types of samples were centrifuged (15,000 r.p.m.) at 4° C for 1 h. The supernatant was used for electrophoretic separation. Both methods gave the same number of isoenzymes, which indicates4,9 that no new spots were produced by this technique.

For electrophoretic separation, a 10 per cent starch gel¹⁶ in 0.015 molar citric acid and 0.05 molar tris (pH 7.2) was used. Vessel buffer consisted of 0.063 molar citric acid and 0.42 molar tris (pH 8.6). The voltage gradient was 4.5 V/cm and electrophoresis lasted about 20 h at 4° C. Staining of isoenzymes was carried out by the Wieme method¹¹ for agar gel zymograms.

Extract of spermatozoa contained the same five isoenzymes which are found in tissues. In each sample investigated, one of three different types of a second LDH isoenzyme system was discovered (Fig. 1a and b). The two types (I and II) are usually composed of five different spots. As Fig. 1 shows, the two types differ in electrophoretic mobility. Type III is composed of several spots with an intermediate mobility. The spot in medium of types I or II (the homotetramers, C4 or C4') usually has the greatest activity and the activities of the other spots decrease markedly towards LDH1 and LDH5.

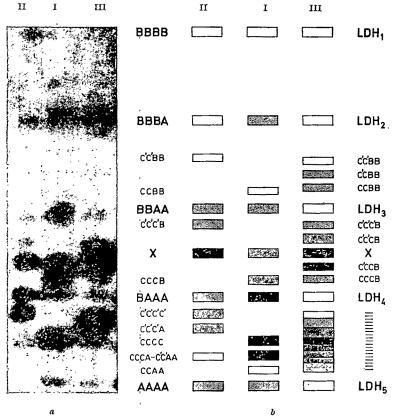

The relative mobility rate of the new system to the LDH₁₋₅ system is decreasing when either ionic strength is lowered or pH is increased in the gel buffer. When different starch gel concentrations (8-16 per cent) are used, and all other conditions are the same, the relative These findings not only mobilities are unchanged. indicate that the extra spots are different from isoenzymes of the LDH₁₋₅ system but also that the mole-

cular size is probably very similar. When more than 5 μ l. of a 50 per cent 2-mercaptoethanol solution is added to 0.1 ml. of samples of types I and II just before electrophoresis, all spots, except the spots C_4 and C_4 , are gradually inhibited (Fig. 2). When 25 μ l. is used, only C_4 and C_4 may be visible and for type III only five spots persist in the area between C4 and Ca

Results of heat inactivation showed that isoenzymes composed of C or C' sub-units are relatively thermostable and when samples are heated for 1 h at 60° C before electrophoresis only these fractions are visible. These findings indicate that the isoenzymes, which are not inhibited, are controlled by a third locus C and are of a tetrameric structure.

Table 1. THE DISTRIBUTION OF TYPES I, II AND III OF A SECOND LDH ISOENZYME SYSTEM FOUND IN BOAR SPERMATOZOA

Phenotypes	I	II	III	Total
No.	32	15	44	91
Percentage	35-3	16-5	48·2	100

second LDH isoenzyme system in boar spermatozoa. b, Schematic picture. Fig. 1. a, Three types of a

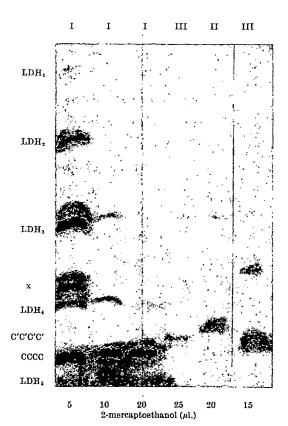

Fig. 2. Inhibition of LDH isoenzymes by using different amounts of 2-mercaptoethanol.

When a recombination technique is used4,5,9,12 involving the addition of a skeletal muscle extract, the activity of homotetramers and isoenzymes from the LDH₁₋₅ system decreases, and spots situated towards LDH, increase, and, furthermore, an extra spot is formed in front of LDH₅. A similar phenomenon can be seen on the opposite site of the homotetramers, when heart muscle extract is used. The same trend was also seen when the heterozygote type (III) was used.

The relative mobilities, number of spots in types I, II and III (see Fig. 1b) and the formation of extra spots when recombination is used, are all in agreement with the hypothesis that isoenzymes of the new system are tetramers composed of sub-units of C, C+B or C+A. The frequency of the polymorph types is relatively high (see Table 1).

A preliminary investigation of the genetic basis of the system has been carried out and so far we have found no evidence against our claim that the different types are genetically controlled.

The behaviour of band x (see Fig. 1b)

differs in some respects from that of the two LDH systems. The mobility of this fraction is the same in all three types (Fig. 1). Activity is not much changed when the recombination technique is used. When phenazine methosulphate is omitted from the staining solution and zymograms are subjected to 37°C for 12 or more hours, a pink spot is seen

in the position of band x. A similar pink spot can be seen in the area of LDH₃, and this spot is relatively stable when butanol is used for inhibition. In these two respects, this x-band shows a behaviour similar to the x-band in rat kidney^{13,14}. When samples are subjected to 60° C for 30 min or when 15 µl. of a 50 per cent solution of 2-mercaptoethanol is added to a 0.1 ml. sample, only the two spots and homotetramers controlled by the Clocus are not inhibited. These facts seem to indicate that these fractions are part of a third system.

In vivo Interaction of 4-Nitroquinoline-I-oxide and its **Derivatives with DNA**

4-NITROQUINOLINE-1-OXIDE (4NQO) is a highly carcinogenic compound. The reductive pathway, which yields 4-hydroxylaminoquinoline-1-oxide (4HAQO), was thought to be essential for its carcinogenic mechanism^{2,3}. There have been reports of the interaction of 4NQO or 4HAQO with DNA in vitro4-8 and in vivo7. This communication deals with the correlation between carcinogenicity and in vivo interaction with DNA by 4NQO derivatives.

4NQO or its derivatives (1 mg/rat) was injected intraperitoneally into Donryu rats bearing Yoshida ascites hepatoma AH 130. One hour later, the hepatoma cells were collected and DNA was extracted by the method of Kay et al.8.

Fluorescence with maxima at 465-475 mu when excited at 365 mµ was observed in DNA isolated from hepatoma cells of rats injected with carcinogenic 4NQO, 4HAQO or 6-chloro-4-nitroquinoline-1-oxide (6-Cl-4NQO), but not from hepatoma cells of rats injected with non-carcinogenic 4-aminoquinoline-1-oxide (4AQO) or 3-methyl-4-nitro-quinoline-1-oxide (3-CH₃-4NQO). The radioactivity in DNA isolated from hepatoma cells of rats injected with 1 mg of $^{14}\text{C-4NQO}$ (3×10^5 c.p.m./mg) shows that 1.7 moles of quinoline compound was bound with a mole of DNA, if the molecular weight of DNA is 6.7×10^8 (Table 1).

The fluorescent compound in DNA was not eliminated from single strand DNA by heating and rapidly cooling native DNA (Table 1), which suggests that there is a covalent bond between the quinoline compound and the DNA molecule.

Table 1. Fluorescences of native and heat-penatured dnas from AH 130 treated $in\ vivo$ with 4ngo and 7ts derivatives

Injected	Carcinogenicity	Fluorescence (relative intensity/ E_{zee})		
		Native	Heat-denatured	
4NQO	+	10.4	10.1*	
4NQO	+	14.3	13.3†	
14C-4NQO	+	11.8		
4HAQO	+	15.3	15-8*	
6-Cl-4NQO	+	19.0	-	
4AQO	<u> </u>	Ō	0*	
3-CH ₂ -4NQO		Õ		
Salina		ň	n•	

* DNAs isolated by ethanol precipitation. † DNAs isolated on a column of 'Sephadex G-25'.

The reductive pathway to yield 4-hydroxylamino derivatives seems to be necessary to form fluorescent compound in DNA and exert carcinogenic action, because 3-CH₃-4NQO, which cannot be reduced by an enzyme, did not produce fluorescent compound. The more reduced compound 4AQO, which is not carcinogenic, did not produce fluorescence in DNA.

Isonicotinic Acid Hydrazide as an Inhibitor of Transpeptidation: Relevance for Blood Coagulation

WE have found that isonicotinic acid hydrazide, a widely used drug1, is a potent inhibitor of the crosslinking of This reaction constitutes the terminal step in normal blood coagulation and proceeds by way of an enzyme catalysed transpeptidation by forming inter-fibrin γ -glutamyl- ϵ -lysine bonds^{2,3}. Compounds which resemble the donor (amine) or the acceptor (carbonyl) side-chain functions of fibrin specifically inhibit the crosslinking reaction without, however, interfering with gel formation -that is, clotting time—itself.

Table 1 Type of label and ref. Amine tracer Carbon-14 isotope^{4,5} Chemical⁵ Glycine ethyl ester Hydroxylamine
Hydrazine
N-(5-aminopentyl)-5-dimethylamino-Chemicals Fluorescences

The compounds listed are sufficiently different in the basicity (nucleophilicity) of amines and in the substituent groups to permit the conclusion that most, if not all, amine inhibitors $(H_2N.R)$ would block the crosslinking sites of fibrin in a similar manner

$$H_2N \cdot F \cdot CO \cdot Y + H_2N \cdot F' \cdot CO \cdot Y \xrightarrow{\theta} H_1N \cdot F \cdot CO \cdot NH \cdot F' \cdot CO \cdot Y + HY$$
 (1)

$$H_2N \cdot F \cdot CO \cdot Y + H_2N \cdot R \xrightarrow{e} H_2N \cdot F \cdot CO \cdot NH \cdot R + HY$$
 (2)

where reaction (2) competes with the crosslinking process (1), shown for dimerization by a single amide bond (k and k' represent fibrin; e stands for the crosslinking enzyme, that is, the thrombin-activated fibrin stabilizing factor."; Y is the leaving group in transpeptidation).

Highly potent inhibitors were found among primary amines, aminoxy compounds and hydrazine derivatives. Apart from usefulness in elucidating the mechanism of crosslinking, such inhibitors may be of pharmacological significance. Thrombi formed in the presence of these compounds are very much more susceptible to attack by lytic enzymes.

Details are available of the mode of action of the donor type of inhibitors. Four of these (Table 1) were shown to serve as substrates for the crosslinking enzyme. As such, they could be incorporated into fibrin and were, in fact, indispensable for determining the nature of acceptor and donor sites on the protein.

Isonicotinic acid hydrazide

1-naphthalenesulphonamide

$$\left[R' \cdot \text{CO} \cdot \text{NH} \cdot \text{NH}_2; \right] = R'$$

is the most potent inhibitor found so far. In the isolated bovine fibrin crosslinking test system (Fig. 1), its inhibitory effect may be readily demonstrated even in concentrations close to those obtained in plasma during the pharmacological administration of the drug1.

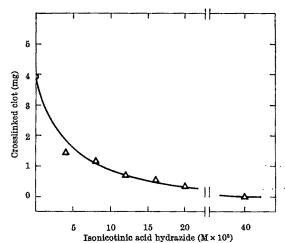

Fig. 1. Inhibition of fibrin crosslinking by isonicotinic acid hydrazide (Calbicohem, lot 105421). Ordinate denotes the amount of fibrin which cannot be dissolved in 1 per cent monochloroacetic acid. For detailed methodology see refs. 4 and 14.

There are clearly several ways in which isonicotinic acid hydrazide could exert an inhibitory effect on fibrin crosslinking, but only a few possibilities will be indicated here, pertaining to the assumption that it serves as a transpeptidating partner. Isonicotinic acid hydrazide might react either as a pseudodonor or as a pseudoacceptor substrate with fibrin, for example

 $R' \cdot CO \cdot NH \cdot NH_2 + H_2N \cdot F \cdot CO \cdot Y$ $H_*N \cdot F \cdot CO \cdot NH \cdot NH \cdot CO \cdot R' + HY$ $R' \cdot CO \cdot Y + H_2N \cdot F \cdot CO \cdot NH \cdot NH_2$

 $R' \cdot CO \cdot NH \cdot F \cdot CO \cdot Y + NH_{\bullet} \cdot NH_{\bullet}$

Future work is planned to decide which, if any, of these possible reactions might have occurred. Meanwhile, preliminary experiments indicate that isonicotinic acid hydrazide also has an effect on reactions involving other transamidating enzymes—for example, guinea-pig liver transglutaminase⁸ and a lobster tail muscle enzyme^{10,11}. A general effect of this sort raises the question whether the antitubercular activity of the drug might not be related to inhibiting a critical transpeptidase reaction in mycobacterium. It is interesting to note that another antibiotic, penicillin, functions through inhibition of a cell wall transpeptidase12,13.

Rate of Release of Iron from Ferritin to 1,10-Phenanthroline

Although the uptake and release of iron from ferritin, the principal form in which iron is stored by mammals, have been examined qualitatively and the rate of uptake has been studied previously2, there have been no previous studies of the rate of release of iron. We report here the results of a study of the rate of in vitro release of iron from ferritin in the presence of 1,10-phenanthroline. The effects of ascorbic acid, as well as concentration and temperature, were determined.

Thermostatically controlled solutions of ferritin (cadmium free) and 1,10-phenanthroline were mixed with care to avoid frothing or excessive shaking of the solutions. The mixtures were then returned to the constant temperature bath and the absorbance at 510 mµ was measured as a function of time. The solutions of iron(II) 1,10-phenanthroline complex which are formed, obey Beer's law for the concentrations studied $(1 \times 10^{-5} \text{ to } 10 \times 10^{-5})$ molar) with an absorbancy of 1.15 × 104. The reactions were followed until the absorbances were greater than 2. This represented a release of 12 per cent of the iron from ferritin and required a minimum of 60 days at 25° C for the systems of lowest ferritin concentration. pH was measured periodically and showed a very slight increase during most runs but remained in the range 7.65 ± 0.30 . Vigorous shaking of the ferritin solutions accelerated the release of iron.

Data were obtained in the form of the concentration of released iron as a function of time. The total amount of iron was known from an analysis of the ferritin used. The absorbance increased only to a point at which about 12 per cent of the iron was released, and this apparently represents an equilibrium state. The logarithm of the amount of iron remaining in the ferritin was plotted against time. An example is shown in Fig. 1. There is an initial portion of the reaction which corresponds to the rapid release of a small amount of loosely held iron followed by the slower release of a much larger amount. It was concluded that the rate law for the release of iron from ferritin was

$$\frac{\mathrm{d[Fe]}}{\mathrm{d}t} = k[ferritin iron]$$

where [Fe] represents the concentration of iron in the solution and [ferritin iron] represents the amount of iron remaining in the ferritin.

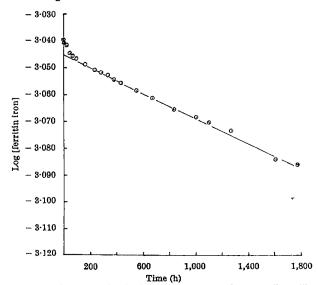

Fig. 1. First order plot for the reaction of 1,10-phenanthroline with ferritin at 25° C. Log [ferritin iron] is the logarithm of the concentration in moles/l. of Iron which remains with ferritin and is uncombined with 1,10-phenanthroline at time t. Initial concentrations: 1,10-phenanthroline (0.0063 molar); ferritin (0.000914 moles of Iron/l.).

The rate constants for the release of iron from ferritin in the presence of 1,10-phenanthroline are given in Table 1. Average values of the rate constants at various temperatures were used to obtain the activation energy for this process, which was 13 ± 2 kcal/mole. The frequency factor was found to have the extremely low value of about 10¹ sec-1. In solutions where the initial concentration of 1,10-phenanthroline was varied twenty-five fold and the initial concentration of ferritin was kept constant, the rate constants showed no change within the experimental error. This requires a mechanism which is independent of the concentration of the 1,10-phenanthroline. It is probable that the rate determining step is the slow release of iron from micelles in the interior of the ferritin macromolecule and its transport to the surface of this species. In this case it is followed by two much more rapid reactions: the complexing of the iron(III) by the 1,10-phenanthroline and the photoreduction of this to the iron(II) complex3. The rate of this photoreduction is more than thirty times greater than the rate of the ferritin-1,10-phenanthroline reaction at 25° C. This explains why the reagent is so effective in removing iron from ferritin as well as the fact that the overall reaction is zero order in this reagent.

A mechanism for this process which is consistent with the data obtained is as follows

iron (III) in phosphate slow iron (III, II) at 1,10-phenanthroline micelles in ferritin → surface of ferritin in releasable form

iron (II) complex with 1,10-phenanthroline.

The rate of release of iron is greatly increased by the presence of ascorbic acid (compare Table 1).

Table 1. First order rate constants for the release of iron from ferritin system

		W-2250-2-0		
Tem- perature °C	Initial ferritin (moles of iron/l. × 104)		Initial 1,10- phenanthroline (moles/l. × 10 ⁴)	$k \times 10^4$ h ⁻¹
25.0	4-89 9-14 14-66 18-28 27-42		63	0.28 0.53, 0.56, 0.47 0.53 0.34, 0.29, 0.30 0.32
37.5	4·89 9·14 14·66		63	Mean 0.40 (±0.11) 1.21 1.33, 1.04 0.97, 0.88
50.0	4·89 9·14 14·66		63	Mean 1·1 (±0·1) 0·79 1·99, 4·48, 1·82 1·49, 1·85
25.0	9·14		2·5 12·6 25·0 37·8 50·4	Mean 2.1 (±0.8) 0.48 0.29 0.35 0.27 0.31
37·5 25	9·14 4·89	0·03 0·06 0·48 0·60	12·6 63	Mean 0.34 (±0.06) 1.49 0.63 2.52 16.0 24.3

A plot of the rate constants of Table 1 against the concentrations of ascorbic acid is roughly linear, indicating that the reaction in this case has the rate law

rate =
$$\frac{-\text{d[ferritin Fe]}}{\text{d}t}$$
 = k[ferritin Fe] [ascorbic acid]

These results provide detailed expressions for the rate of release of iron from ferritin which are consistent with the known properties of this species. They also provide a method for measuring this release which can be used in other quantitative rate studies of this process.

Radiotracer Determination of Supernatant Liquid entrapped among Centrifuged Red Blood Cells

WE are conducting experiments to measure the rate of permeation of glycerol through the red blood cell membrane. The procedure involves mixing glycerol solutions with red blood cells and letting them stand for different periods of time, then centrifuging the mixtures to separate supernatant glycerol solution from the red blood cells containing glycerol. The red blood cell fractions are then analysed chemically for glycerol content. The question arises as to how much glycerol solution is entrapped among the red blood cells after centrifugation. The answer to this question would have some effect on the results of analyses for glycerol in the red blood cells with subsequent effects on the permeation rates; a knowledge of the amount of extracellular glycerol will enable us to make proper corrections. The present experiment was carried out to determine the percentage of extracellular glycerol.

The experimental procedure involves mixing a radioactive carbon-14 sucrose solution with packed red cells. A count of this original solution is taken. Sucrose does not penetrate the cell wall. The mixture is then centrifuged, and the supernatant solution is removed. An equal mass of non-radiactive sucrose solution is added to the red cells and another count taken. The geometries of the original and final solutions are similar; this ratio of the final count to the original count gives a measure of the fraction of supernatant liquid entrapped among the red

In our first experiment, a 4.0 g sample of packed red cells in a 15 ml. test tube was mixed with 4.0 g of a 7 per cent sucrose solution containing carbon-14. The specific gravity of the red blood cells is about 1.09 (ref. 2). The specific gravity of the 7 per cent sucrose solution at 60° F is 1.03, about the same as blood serum. sample (1 g) of this mixture was counted with an endwindow Geiger counter. The net count, averaged for a 10 min period, was 4,293 c.p.m. The mixture was then centrifuged in a clinical model centrifuge at 3,300 r.p.m. (top speed) for 10 min. The centrifugal force was 1,720 times the force of gravity.

Next, the supernatant sucrose was removed, together with the uppermost portion of the red blood cells, by aspiration. The remaining red cells were weighed and an equal mass of non-radioactive sucrose was added. This mass was then mixed for 1 min. A sample (1 g) was removed and counted. The net count, averaged for 10 min, was 339 c.p.m. From these data, the amount of sucrose entrapped among the red blood cells after centrifugation is calculated to be 7.9 per cent.

This experiment was repeated. The radioactivity of the original mixture, averaged for a 10 min span, was 4,658 After centrifugation, removal of supernatant liquid and dilution, the radioactivity was 334 c.p.m. In this second experiment, the amount of sucrose entrapped among the red blood cells after centrifugation was 7.2 per cent. The average of the two experiments is 7.6

A test was made to evaluate the possibility that some sucrose had permeated the red cell wall, changing the meaning of the results. The final blood and sucrose solution from the first experiment was diluted with a large amount of non-radioactive sucrose. If the radioactive sucrose were inside the red cell, the dilution and subsequent removal of supernatant would not substantially reduce the radioactivity of the red cells; the radioactivity would remain at approximately 339 c.p.m. On the other hand, if sucrose was entirely extracellular, the dilution, centrifugation, removal of supernatant and redilution to 1:1 should reduce the radioactivity substantially. It was found that the radioactivity was reduced to a very small

reading, just slightly above background, after these steps were taken. It is concluded, therefore, that sucrose does not permeate the red cell wall.

Thus centrifugation of blood at top speed in a clinical laboratory centrifuge for 10 min can leave as much as 7.6 per cent of the supernatant liquid entrapped among the red blood cells. Sucrose does not permeate the red blood cell wall.

Isoenzymes of Phosphoglucose Isomerase in Mice

A PROCEDURE has been developed for the visualization of the glycolytic enzyme, phosphoglucose isomerase, after electrophoresis in a starch gel. The staining mixture applied to the sliced gel surface consists of fructose-6phosphate (free of glucose-6-phosphate), glucose-6-phosphate dehydrogenase, NADP, phenazine methosulphate and the tetrazolium salt MTT. The formation of glucose-6-phosphate by the isomerase is coupled to the reduction of the tetrazolium dye, which turns blue.

No heterogeneity has yet been observed for phosphoglucose isomerase in human haemolysates, but variant isoenzymes were found when haemolysates from a number of wild mice (Mus musculus) were examined, and a similar type of polymorphism was also encountered in haemolysates and muscle extracts from various strains of laboratory mice. Inserts (a) and (c) in Fig. 1 are from a pair of wild mice, and it can be seen that insert (a) gave a single enzyme band migrating significantly nearer to the anode than the single more cathodically migrating band seen in insert (c). When the mice of this pair were crossed they produced progeny of both sexes, all of which gave triplet pattern shown in insert (b); the most anodically migrating band of the triplet was indistin-

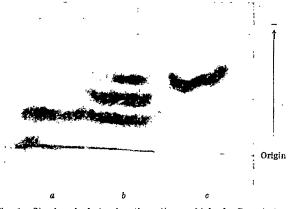

Fig. 1. Starch gel electrophoretic patterns obtained after electrophoresis of mouse haemolysates and specific staining for phosphoglucose isomerase. Haemolysates were made and electrophoresis was carried out as described befores, but metal cooling plates were used with a potential difference of 20 V/cm for a period of 4 h. The staining mixture applied to the gel surface was made by mixing 0.3 molar tris buffer at pH 8·0 (1·5 ml.), 0·1 molar magnesium chloride (0·5 ml.), 18 mmolar sodium fructose-6-phosphate (0·2 ml.), 6 mmolar NADP (0·1 ml.), purified glucose-6-phosphate dehydrogenase (0·2 ml. of a solution containing 10 V/ml.), MTT (1 mg) and phenazine methosulphate (0·5 mg), just before use. It is important for the fructose-6-phosphate to be free from glucose-6-phosphate, and in this laboratory it is prepared as needed by the acid hydrolysis of crystalline trisodium fructose diphosphate. Inserts (a) and (c) contained haemolysates from a breeding pair (see text), and insert (b) contained haemolysate from one of the progeny.

guishable in mobility from that appearing on its own at insert (a); the most cathodically migrating band was likewise indistinguishable from the one appearing on its own at insert (c), and the third band of the triplet had intermediate mobility. This situation, which is analogous to that found for the enzyme phosphogluconate dehydrogenase¹⁻⁴, and for certain other enzymes⁵⁻⁷, is consistent with a dimeric structure for the enzyme phosphoglucose isomerase, and indicates that this enzyme in mice is likely to be controlled by an autosomally linked locus.

We thank Mr R. Redfern and his colleagues of the Ministry of Agriculture, Fisheries and Food, Tolworth, for the wild mice.

Fractionation of Protein Solutions by Membrane Partition Chromatography

HIGH flux preformed ultrafiltration membranes, serving as diffusive barriers to the transport of macromolecular species, have been found to be extremely useful for: the non-denaturant concentration of dilute protein solutions1; as a practical means of rapid dialysis and evaluation of micro-ion binding phenomena; for separating the products of proteolysis during digestion (unpublished work of Blatt, Robinson, Zipilivan and Hudson); and in the determination of lower molecular weight moieties2. These membranes are hydrous gels formed from the complex interaction product of polyanions and polycations and are marketed under the name of 'Diaflo' by the Amicon Corporation, Cambridge, Mass. The molecular weight retentive capacities of these membranes, 'UM-2' and 'UM-1', have been arbitrarily fixed at 500 and 10,000, respectively. In a recent study, a gel membrane with a more expanded structure (exclusion limit molecular weight 35,000) was investigated as a partitioning device in the removal of the albumin impurity from crystalline alpha lactalbumin3. Whereas these membranes are non-porous hydrous gels, ultrafilters with exclusion limits in excess of 40,000 require pored structures for formulation.

Five membranes (arbitrary molecular weight exclusion limits in parenthesis) were evaluated for their protein retentive properties: (a) 'XM-100' (100,000); (b) 'XM-50' (50,000); (c) 'XM-4a' (35,000); (d) 'UM-1' (10,000) and (e) 'UM-2' (500). A modified ultrafiltration cell', similar to that used for the evaluation of proteolysis, was used (Fig. 1). In this system, a non-pulsatile buffer flow is established and the ultrafiltrate is passed through the ultraviolet monitoring system until baseline stability is achieved. The pump and ultraviolet analytical system are components of the 'Spectrochrom' apparatus, Beckman Instrument Co., Fullerton, California. After equilibration the protein solution is injected into the sampling valve and the absorbance of the ultrafiltrate recorded at 280 mu. In all studies, 1 ml. of 1 per cent protein solutions,

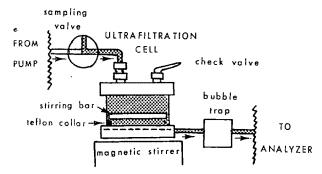

Fig. 1. Constant flow ultrafiltration cell (16.5 ml. capacity) with buffer and sample introduction valve, ultrafiltrate egress port, bubble trap and entry to the ultraviolet analytical system. The dashed line above the stirrer denotes the ultrafiltration membrane.

in phosphate buffered saline, pH 7·4, were first injected into cells without membranes and then through each membrane system (vide supra). The amount of protein is calculated from the differential peak areas of the ultrafiltrates relative to the area of the non-membrane system. With bovine serum albumin (Fig. 2), no retention was observed when a filter with a limit of 100,000 was used. With the 'XM-50' filter, however, there was considerable retention of albumin.

The retentive capacities of the different ultrafilters for a variety of proteins are summarized in Table 1. Because many of the commercial preparations contain impurities which could partially invalidate the results, we selected protein standards which have been used in the determination of molecular weights by gel diffusion chromatography. The heavy line serves to bracket the principal exclusion range (>60 per cent retention). From the data, it is apparent that the selected exclusion limits, based upon other model compounds, are only arbitrary and true characterization of retention entails more than the gross molecular weight. In a further series of studies using polyethylene glycols of graded molecular weight, complete diffusivity through the membranes was observed for molecules far in excess of the limits stated. This passage we attributed to the linear structure of the polymer, which makes it possible for properly oriented molecules to pass through the membrane structure. The limited diffusivity of essentially uniform proteins (for example, albumin and haemoglobin on the 'XM-50' filter) may therefore be caused by a portion of the protein being affixed to the surface or entrapped within the membrane matrix thus altering its retentive capacity.

On the basis of the observed exclusion limits, a tandem assembly was devised consisting of three of the ultrafiltration units shown in Fig. 1 placed in series, each with

a progressively lower exclusion filter (50,000: 10,000:500). In evaluating this system, 80-100 mg of the following mixtures in phosphate buffered saline, pH 7.4, was used: (a) albumin, cytochrome c, cyanocobalamin (vitamin B₁₂), and phenylalanine; (b) aldolase, ovalbumin, cytochrome c and cyanocobalamin. These mixtures were introduced into the upper cell (the other cells were previously filled with buffer) and a buffer reservoir attached. Nitrogen pressure (50 p.s.i.) served to pump buffer through the fluid filled system to effect parti-With these mixtures, flow rates of 10-15 ml./h were achieved. Separations were done at 5° C using total ultrafiltration volumes of 150-175 ml. The final ultrafiltrate (<500) was concentrated by flash evaporation; material found in each of the cells was reduced to 3 ml. by concentration on its own filter. These fractions were then evaluated by reverse flow chromatography on 'Sephadex

 $G\text{-}100^\circ$ (1·0 × 22 cm column) using the 'Spectrochrom'. Admittedly, a longer column would have afforded better resolution, but in the interest of easy handling the smaller column was used. The partition schema and the chromatographic analysis of starting materials contrasted with the filter separated fractions are shown in Figs. 3 and 4. A transition of high to lower molecular weight species was accomplished by the graded retention filters. Furthermore, these separations were in accord with what had been predicted on the basis of the single system evaluation (Table 1). Diffusivity of a given protein through these membranes does not seem to be altered by using a protein mixture.

Values in parentheses represent arbitrary cutoff limits ascribed to the various membranes.

* Membrane plugging was observed with these compounds as evidenced by a considerable increase in pressure during ultrafiltration. This was not observed in the non-porous membranes (35,000 and less).

† With the other compounds, diffusivity, where present, was effected at a rate comparable with the clearance observed in a non-fliter system. With cyanocobalamin, however, a slow escape was noted and, given sufficient time, complete passage through the membrane was obtained.

Systems using the 'UM-100' filter with different mixtures have been evaluated, but with less success. The larger molecular weight materials (for example, gamma globulin and apoferritin) show a tendency to plug the filter when used for protracted periods, and, as such, interfere with passage of material usually diffusible through these membranes. If charge sites could be included within the structure of the membrane, selective rejection of gamma globulin with admission of the species of different charge and of lesser size might be effected. In addition, because these membranes can be tailored to different exclusion limits, tandem systems can be devised for the separation of proteins more similar in molecular weight than those selected for evaluation.

The chief advantage of this ultrafiltration technique is its ability to resolve complex mixtures into size graded

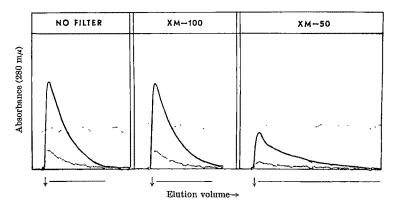

Fig. 2. The absorbance (logarithmic) at 280 m μ of the ultrafiltrate of bovine serum albumin through filters graded at 100,000 and 50,000 exclusion limits, respectively, contrasted with a non-filter system. Flow rate was 54 ml./h and total protein was approximately 10 mg.

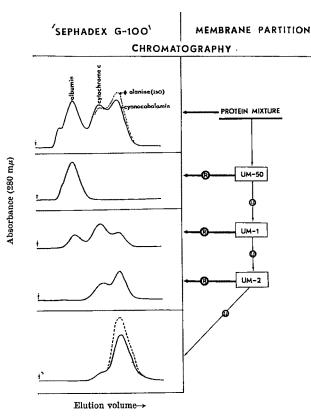

Fig. 3. The membrane separation schema and the 'Sephadex G-100' separation patterns of the following protein mixture: albumin, cytochrome c, cyanocobalamin, and phenylalanine. Flow rate was 10-15 ml./h, and temperature was 4° C. R, Retentate; U, ultrafiltrate.

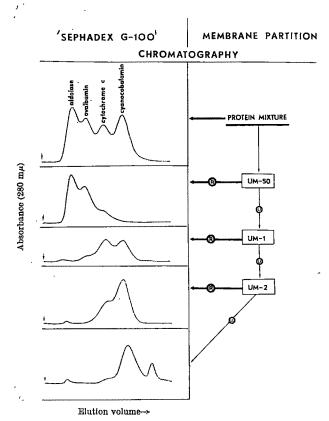

Fig. 4. The membrane separation schema and the 'Sephadex G-100' separation patterns of the following protein mixture: aldolase, oval-bumin, cytochrome c, and cyanocobalamin. Flow rate was 10-15 ml./h, and temperature was 4° C. R, Retentate; U, ultrafiltrate.

classes without the use of precipitating agents, cumbersome electrophoretic methods or the necessity for column chromatography. Increases in the separation rate, as well as the amount fractionated, can be obtained by increasing the surface area of the filter. In that limited fractionation rather than total resolution is achieved, "membrane partition chromatography" seems to be an apt title for this preparative technique.

Possible Conformations of 5S Ribosomal RNA

THE determination of the nucleotide sequence of two 5S ribosomal RNAs by Brownlee, Sanger and Barrell represents a major advance in our knowledge of the structure of ribonucleic acids¹. This RNA contains only the four normal bases A, U, C and G, and so it is an ideal system on which to test some of the physico-chemical techniques known to be sensitive to the conformation of nucleic acids in solution²⁻⁴. There is a wide range of plausible secondary structures which can be devised for 5S ribosomal RNA. The model conformation suggested by Brownlee et al. contains a relatively small percentage of base paired residues. It is possible, however, to design other models in which a much larger number of nucleoside residues is formed into double strand helices. One such model is illustrated in a two dimensional projection in Fig. 1. The remarkable property of this hypothetical conformation is the large fraction of residues in uninterrupted double strands. The number of residues involved in base pairing varies from 82 to 98 out of a total of 120. depending on the identity of the base in position 13 and on whether G-U pairs, two single base pairs and one loop with only two residues are included. The base composition of the 5S ribosomal RNAs would permit a theoretical maximum of 112 base paired residues. In our model as much as 87 per cent of this maximum is attained. This is a much larger percentage of double strand sections than seems possible for any of the transfer RNAs of known sequence5-8

The hypothetical 5S ribosomal RNA structure shown in Fig. 1 is consistent with the general picture of RNA conformation which has emerged from studies on smaller model compounds. Most of the base paired sections contain four or more nucleotide residues. Shorter double or triple strand oligonucleotide complexes have been observed to form only in extreme environmental conditions!. The number of bases looped out of helical regions has been kept to a minimum. This takes into account the strong tendency of single strand oligonucleotides or even individual nucleosides to form stacked arrays^{8,10}. Uridylic acid occurs at almost all places in the structure where an abrupt bend, hair pin turn or junction of two helices is

postulated. The vertical stacking interactions of U are much weaker than the other bases, and so its presence at positions number 14, 25, 32, 40, 65, 80, 89 and 111 should minimize the energy necessary to interrupt the helices at these points. One double strand section is connected by a loop containing only two residues. This may be possible if one of the base paired residues adjacent to the loop has the syn conformation found occasionally in crystals11 instead of the anti conformation usually thought to exist in solution. Alternatively, a larger loop may be formed instead of the extra base pair.

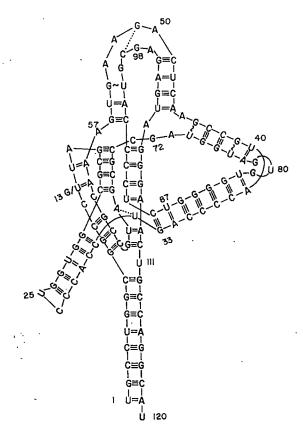

Fig. 1. Two dimensional projection of a possible conformation for the 5S ribosomal RNA in which up to 98 of the 120 nucleoside residues are base paired. Normal G-C and A-U pairs in helical regions are connected by three or two lines, respectively. G-U pairs are indicated by a tilde and two possible single base pairs are shown by a dotted line.

Spectroscopic techniques are available which make it easy to distinguish a mostly double strand structure such as the one shown in Fig. 1 from a model in which little base pairing occurs. As an example, the calculated optical rotatory dispersion of three possible conformations for the 5S ribosomal RNA is shown in Fig. 2. These calculations are performed as described previously for transfer RNA except here the problem of how to estimate the contribution from strange bases does not arise2. The three models used to compute the spectra in Fig. 2 are: (a) a completely single stranded RNA; (b) an RNA containing the twenty-three base pairs suggested by Brownlee et al.; and (c) the model with forty-nine base pairs shown in Fig. 1. The optical properties of G-U pairs are unknown, and so they were neglected in the calculations. should have only a very small effect. Models (b) and (c) contain only three G-U pairs each. The large difference in the calculated optical rotatory dispersion for the three models is best illustrated by the position of the longest wavelength cross over. This occurs at 279 mu, 273 mu and 263 mu for, respectively, zero, twenty-three and forty-nine base pairs. Thus even a qualitative measurement of the optical

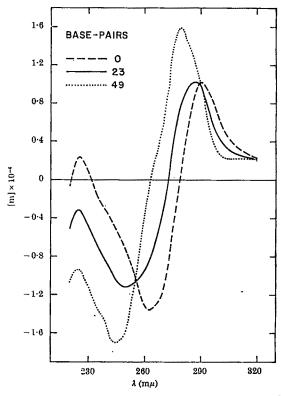

Fig. 2. Calculated optical rotatory dispersion curves for three possible conformations of 5S ribosomal RNA.

rotatory dispersion of the 5S ribosomal RNA should permit the approximate degree of base pairing to be established.

Note added in proof. Preliminary measurements of the optical rotatory dispersion of 5S ribosomal RNA indicate a crossover at 264 mu. This strongly suggests a conformation in which extensive base pairing occurs.

Coupling of Enzymes to Cellulose using Chloro-s-triazines

Many methods are now available for coupling enzymes and other biologically active compounds to solid supports¹⁻⁴. Most involve the preliminary preparation of a special support or of a special derivative of a general support such as cellulose; for example, the carboxymethyl or p-amino-benzyl ether derivative. We have therefore sought coupling reagents which allow a more direct approach and have developed the use of cyanuric chloride and dichloro-s-triazines. The latter can be prepared as stable compounds with solubilizing groups such as carboxy-methoxy or carboxy-methylamino, which make them very convenient reagents.

Table 1. condition for the reaction of chloro-8-triazine with cellulose and of the product of this reaction with chymotrypsin

Any unreacted chlorine should be reacted subsequently with 1 molar ammonia-ammonium chloride buffer.

One of the chlorines is sufficiently reactive to react in a few minutes with cellulose in aqueous solution at pH 9-11 (Table 1) to give good yield of the monochloro-s-triazinyl-cellulose complex. Stronger nucleophiles, such as the —NH₂ group of amines, amino-acids and proteins, will then react with the second chlorine in mild conditions, 0°-20° C and pH 8·6 in times of the order of 16 h, that is

Using this method we have been able to couple chymotrypsin to prepared cellulose (Whatman Standard Grade Cellulose powder) so that the product contains 1-2 per cent by weight of enzyme protein with 25 per cent of its free solution activity. Such products retain up to 60 per cent of their initial activity for 2-2.5 yr when stored as suspensions in distilled water at 2° C.

We have also developed conditions in which it is possible to react cyanuric chloride with cellulose and still retain two of the chlorine atoms. Cellulose is treated with normal sodium hydroxide, the excess removed by filtration and the product added to an acetone solution of cyanuric chloride. Water is at once added and the acid generated by the hydrolysis of cyanuric chloride reduces the pH of the reaction mixture sufficiently rapidly to prevent the hydrolysis of a second chlorine. After a contact period of 10–15 sec, the mixture is quenched in 20 per cent acetic acid and washed in cold acetone and water mixtures. The dichloro-s-triazine cellulose so formed is extremely reactive towards proteins. It will react with chymotrypsin in a few minutes at pH 7.

Any of the second chlorines remaining together with all of the third chlorines may be removed by reaction

Cell—OH + Cl
$$N$$
 \rightarrow Cell—O— N \rightarrow Cl N \rightarrow NH—Protein \rightarrow Cell—O \rightarrow NH—Protein

with an amine; for example, molar ammonium hydroxide-ammonium chloride buffer, pH 8.6. The rather lower reactivity of the enzyme obtained by this method (5 per cent of its free solution activity) could almost certainly be improved by using shorter contact times.

Because of the mild treatment that the cellulose undergoes in all these processes, the method can be used for all forms of cellulose, for example, paper and cotton cloth. It may be applied also to other nucleophilic polymers such as crosslinked dextrans, starch, polyvinyl alcohol, wool and possibly nylon. Work on these problems is continuing.

Processes described in this communication are the subject of UK patent application 30615/67, rights in which have been assigned to NRDC.

PSYCHOLOGY

Pupil Size as a Measure of Arousal during Information Processing

Following the work of Hess^{1,2}, and in parallel to other recent work³ where changes in the size of the pupil of human subjects' eyes were found during information processing tasks, a number of further findings are reported here. Variations in the level of arousal are presumed to be the intervening variable. A cinematographic technique for recording pupil size has been developed in which very high film emulsion speeds have been attained, in excess of 5,200 ASA from 650/800 ASA Ilford HPS 16 mm ciné film.

In the experiment, two kinds of factor were varied: the type of problem presented, and the required motor response of the subject. The latter included immediate verbal answering on solving the problem, storing the answer until a signal is received, and a substitute activity such as pressing a button. All stimulus material was presented visually on a back-projection screen.

Several findings were made with material involving novel and familiar, comprehensible and incomprehensible cartoon drawings. There was, however, no evidence to link pupillary changes with a like or dislike of the material, nor with the degree of complexity of the stimulus or the information contained in abstract and geometrical drawings. This perhaps conflicts with previous pupillary² and other autonomic^{4,5} findings.

More important, it was found that a peak in the dilation of the pupil was followed by a sharp post-solution drop, when single-solution anagrams and mental-arithmetic division sums were solved. That this drop was associated with a reduction in arousal at the end of a job was demonstrated by the presence of the drop, if not the peak, when the subject was instructed to answer and halt his attention on multi-solution anagram-type word-game problems on receiving a signal. Otherwise, there was no such pupillary drop with the multi-solution problems. Unsolved material, on the other hand, both arithmetic and single-solution anagrams, was found to produce a high plateau of maintained dilation, usually just below the peak attained at solution.

Similarly, difficult arithmetic problems, solved or unsolved, were found to produce an overall higher level of dilation than easy ones. Moreover, the same phenomenon occurred when the same kind of arithmetic material (with answers consisting of two digits) was to be answered by two different techniques, one easier than the other. Thus the cognitively easier response, of giving each of the two digits of the answer as attained, was found to result in a lower level of dilation than when the first digit had to be remembered while the second was being found, and then both being answered verbally together.

The absence of solution peaks with the multi-solution word-game material, the overall relatively low levels even when many responses were made, the lack of differences noted here between material found easy or difficult, or when many or few responses were made, suggested one of two things. Either verbal answering did not account solely for the solution peak (some other factor such as success was perhaps responsible), or the potentially easier multi-solution problem was different in its effect from the single-solution one.

The importance, however, of the contribution of verbalization to the response peak of the pupil was demonstrated in several ways. Verbalization of a stored response, either at a pre-arranged moment, or after receiving a signal, resulted in an increase in the dilation of the pupil during those periods, as compared with control situations when verbalization occurred elsewhere. The moment of actual as opposed to verbalized solution of a problem was still marked by a peak, although often of a somewhat lower level. Other motor activities, however, such as pressing a button on solving the problem, proved sufficient to bring the solution peak up to the same level as when con-Nevertheless, while comitant verbalization occurred. pressing a button proved equivalent to verbalization in forming the peak, it did not replace it. Thus subsequent additional verbal answering of the response resulted in a dilation level equal to that which occurred in a similar condition where there had been no such pressing of a button. It has already been noted here, however, that verbalization was not an inevitable inducer of relative dilation of the pupil, as with the multi-solution word-game material.

There were a number of subsidiary findings. There was a tendency for an overall "down-drift" in the pupillary baselines during the course of the experimental runs, possibly associated with a decline in arousal. These would usually be reset to earlier levels by switching stimuli or response types, or when a number of successive difficulties or failures were encountered. Similarly, overall baselines appeared to be pre-set to blocks or runs of similar stimuli. Thus, during inter-stimulus or inter-task intervals within such blocks of similar material, a baseline pupillary diameter would be found which differed from that encountered with blocks of different material.

Our intention now is to add measurements of blink-rate to the studies of the pupil in information processing tasks.

The latter will include reaction time and vigilance situations, and comparisons of performance under established sets such as speed and accuracy. The effects of drugs, stress and fatigue could also be studied, as well as situations using auditory material such as the Wittenborn⁶ tests of attention, with a button pressing response and a variable rate of presentation.

This work was carried out while I was at the Department. of Psychology, University of Sheffield.

GENERAL

Gymnoplasts instead of "Protoplasts"

MICROBIOLOGISTS call yeast cells and bacteria devoid of their cell wall "protoplasts". According to a 100 yr old definition the protoplast represents the totality of the living cell constituents quite independent of whether the cell is coated by a wall or not. The general cytological term has therefore unfortunately been narrowed by considering the "protoplast" as the result of the removal of the cell wall. In seminars and symposia on "protoplasts", the term is used for a cytological speciality which covers only a small sector of the wide classical concept, as represented by the publications in the journal Protoplasma and the monographs of Plasmatologia which are concerned with all aspects of living matter, and not only with the problem of whether and how the lost cell wall can be regenerated.

The first cytologist to report naked protoplasts of higher plants was Küster², who called them gymnoplasts, in contrast to the dermatoplasts, the normal plant cells with their cell wall. These are clear and logical terms which tell us that there are cells with walls, the dermatoplasts, from which naked protoplasts, the gymnoplasts, can be prepared.

Another scientific misnomer is "spheroplast" for a gymnoplast the cell wall of which is incompletely removed. Most gymnoplasts are perfect spheres as well, and so it is illogical to give to a neutral morphological term such a special meaning. A term ought to express what it means. An incompletely naked gymnoplast could, for example, be called a semi-gymnoplast. Morphological terms are necessary for the description of observed objects, and they should not be used for the characterization of their ontogenetic or functional features. For example, spherosomes which contain hydrolytic enzymes are lysosomes, but probably not all spherosomes belong to that category, and, of course, not all spherical cells are "spheroplasts", that is, cells with incompletely removed cell walls.

BOOK REVIEWS

STATISTICAL MECHANICS

Statistical Mechanics, Thermodynamics and Kinetics By Oscar Knefler Rice. (A Series of Books in Chemistry.) Pp. 586. (San Francisco and London: W. H. Freeman and Company, 1967.) 90s.

In 1930, few chemists were familiar with the calculation of the thermal properties of gases from spectroscopic energy levels through the methods of statistical mechanics. Giauque wrote an explanatory paper in that year in which he showed that it is possible to go from the equations of classical thermodynamics, which he assumed that his readers understood thoroughly, to expressions for the quantal partition functions of the rotational and vibrational motion of molecules. Professor Rice has adopted the same point of view; he says that "Chemistry students, although their mathematical sophistication has increased in recent years, are generally less familiar with probability theory than with thermodynamics". It is not an approach that is widely used, and, indeed, the current fashion is for a combined textbook of statistical mechanics and thermodynamics in which the latter is derived from the former. No doubt Rice, a teacher of long experience, has followed Giauque's route successfully with his senior and graduate students, but it is not one that they will encounter in their outside reading.

The approach from classical to statistical thermodynamics is open to question on several grounds. First, it may not be easier than the conventional route. Many students will follow readily and often blindly quite elaborate mathematical derivations but have difficulty with the abstract notions behind the apparently simple equations of classical thermodynamics. Secondly, the route starts from an equation that is not one of the basic equations of thermodynamics, namely that between an equilibrium constant K and a standard change of free energy, $\Delta G^0 = -RT \ln K$. The transition to statistical mechanics now requires the assumption that "under standard conditions, the entropy per mole is the same for all quantum species". This assumption raises difficulties in the mind of the student who knows that, classically, entropy is defined only for a system in equilibrium, with a Boltzmann distribution over the energy levels. statement can be justified for internal quantal states, but is, of course, quite inapplicable to translational states. Thus the author has to revert to the method of the canonical ensemble to treat the translational motion of monatomic gases in the third chapter, after he has dealt with the complexities of ortho- and para-hydrogen in the second chapter.

Those who are happy with this approach, however, will find here a wealth of illuminating and occasionally unorthodox ideas. The discussions of the topics on which Rice has worked himself are very extensive and in two cases, quantal liquids and chemical kinetics, at a level appropriate to a monograph.

J. S. ROWLINSON

DISTRIBUTION THEORY

Mathematics for the Physical Sciences

By Laurent Schwartz. (Adiwes International Series in Mathematics.) Pp. 358. (Paris: Hermann; London: Addison-Wesley Publishing Company, 1966.) 94s.

This book is a translation from the French original, with modification in various chapters. It is not a book on

"mathematical methods" in the sense of so many English books, but a work in which there is a careful emphasis on the meaning and implication of various mathematical concepts and procedures. It is written by the founder of the theory of distributions, so it is no surprise that this theory is introduced almost at the beginning and used throughout. It must be said that the contact with the physical sciences is disappointingly slight. The first two-thirds of the book is concerned with pure mathematics; and, of the remainder, only one of the three chapters comes within the realm of applied mathematics. Thus mathematical physicists will turn to the book in order to improve their knowledge and understanding of the mathematics they use, rather than to learn that mathematics in the first instance. As an example it is pointed out that there is no such thing as a "Dirac δfunction". The text says: "The properties of the Dirac function are contradictory and such a function could not exist. . . . Naturally, the physicists know very well that they are concerned with a symbolic device and not a 'true' function. It is more prudent to keep the concept of distribution . . . if we wish to do more than find results intuitively which still have to be proved rigorously in terms of distributions".

The first chapter is concerned with preliminary results on series and integration, including Lebesgue integration. The second chapter deals with distributions, including their definition, differentiation and multiplication; and there are sections on topology in distribution space, convergence of distributions and distributions with bounded supports. Then there is a chapter on convolution; this includes examples of convolutions arising in the theory of electric circuits. The fourth chapter, on Fourier series, deals with the convergence of the series in the distribution sense and in the function sense; and it includes a section on Hilbert space. The next two chapters are given to Fourier and Laplace transforms. Chapter seven, the only one dealing strictly with applied mathematics, is concerned with solving equations of vibration, namely, those for strings, membranes and vibrations in three dimensions. The treatment is quite thorough. A short section is also included on the solution of the equation of heat conduction. The book concludes with short chapters on the gamma function and on Bessel functions.

There is a fair sprinkling of exercises throughout the text, these being taken partly from French examination papers. The book will be of value to the advanced student who is strong in pure mathematics. Its chief value lies in the point of view adopted—that, for a proper understanding of the place of mathematics in various physical contexts, an appeal to the theory of distributions is indispensable.

L. S. GODDARD

FOR STUDENTS OF CHEMISTRY

Introduction to Quantum Theory

By Hendrik F. Hameka. Pp. x+276. (New York and London: Harper and Row, Ltd., 1967.) 55s.

The-flow of textbooks on quantum mechanics increases from year to year. This is all to the good and simply a sign of the vitality of the subject which has grown to such an extent that different specialities—solid state physics, quantum chemistry, atomic physics, elementary particle physics and so on—require a preparation which at least differs in emphasis if not in content. At the same time, the universities are trying to have the subject taught for the first time in the earlier years of the undergraduate curriculum. This again is simply a well understood necessity because of the more recent considerable developments in every branch of quantum physics which require that

the student be brought up to the research level in several

steps, extending over two or more years.

Hameka's book is such an attempt to shift the teaching of quantum theory to earlier parts of the curriculum. One feature of this is the care taken to develop all the required mathematics in some detail, witness chapters on differential equations and matrices and determinants. The ground covered is quite standard with a bias towards the needs of quantum chemistry: the final two chapters deal with two electron systems and atoms respectively. The general emphasis is on the Schrödinger equation, its solution in one dimensions, the eigenvalue problem associated with it and the hydrogen atom. A noteworthy feature of the book is the careful treatment of perturbation theory, the variation theorem and the connexion between them. This will be a most useful book, perhaps mainly for those students who wish to go on to do quantum chemistry.

S. ZIENAU

CONTINUUM MECHANICS

Modern Developments in the Mechanics of Continua Edited by Sılamon Eskinazi. (Proceedings of an International Conference on Rheology held at the Pinebrook Conference Centre of Syracuse University, Pinebrook, New York, August 23–27, 1965.) Pp. xii+203. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 80s.

This book contains the text of sixteen papers presented at a rheology conference sponsored by Syracuse University in August 1965. The authors are drawn mainly from the United States, but there are also contributions from Canada, France and Mexico. Five of the papers are concerned wholly or in part with experimental work, while the remaining eleven are entirely theoretical.

Of the experimental papers, two (P. S. Virk et al. and

Of the experimental papers, two (P. S. Virk et al. and A. G. Fabula et al.) are concerned with the Toms effect of drag reduction produced by very low concentrations of certain polymers in solution; the paper by Virk et al. amounts to a brief review article on the subject. A further two experimental papers deal with very different topics in the mechanics of mixtures. D. R. Axelrad and R. N. Yong consider flow of two phase media such as clay, and V. C. Behn and G. A. Strobel describe work on the diffusion of benzoic acid into kaolite slurries. The last paper in this group, by G. B. Thurston, describes experiments on shear wave propagation in birefringent viscoelastic liquids.

Turning to the theoretical contributions, we find that the conference began with some characteristically controversial remarks by C. Truesdell on the subject of thermodynamics. The greater part of Truesdell's paper is devoted to an exposition of work by Bowen and Wang on the formulation of a thermodynamic theory for a class of materials called materials with quasi-elastic response. The next two theoretical papers, by F. W. Smith on the flow and deformation of aggregates and A. J. A. Morgan on constitutive equations in implicit form, are brief accounts of work published more fully elsewhere. Jaunzemis contributes a short but clear description of Cosserat continua, and S. K. Datta investigates numerically the stability of second order fluids in Couette flow. I found the article by A. C. Pipkin on approximate constitutive equations one of the most rewarding in the This discusses the various approximations (for small motions, short motions, slow motions) which can be introduced into the general constitutive equations for non-linear visco-elasticity, and shows clearly their relation to each other and the general theory, as well as pointing out some of the pitfalls awaiting those who apply the approximate equations uncritically. Another fascinating paper is that by R. L. Fosdick on strain compatibility. This not only gives new forms of the compatibility

conditions for finite strain, but also, by a counter-example, disproves Ericksen's conjecture that the only deformations of incompressible materials with constant strain invariants are homogeneous deformations, and so reopens the question of whether there exist further deformations which are possible in all incompressible elastic materials. This paper has been somewhat overtaken by subsequent events, and its value would have been even greater if it had been published earlier. In the remaining papers, C. C. Wang proves a kinematic theorem for a class of motions (motions with constant stretch history), B. D. Coleman and M. E. Gurtin present a simplified onedimensional account of their work on acceleration waves in non-linear materials, and J. Barberan and I. Herrera prove uniqueness theorems for dynamic linear visco-Somewhat out of place is a paper by elasticity. R. Goethals and Th. A. de Roquefort on the theory of jets.

The level and standard of the papers are as diverse as their subject matter. As indicated above, some of the papers are brief accounts of work published elsewhere, some are original research papers, and others are short review articles. This variety makes for a rather untidy volume. Yet again the question arises as to whether any useful scientific purpose is served by the publication of books of this kind. I believe that the best of these papers would have been more accessible more quickly if they had been published in appropriate journals in the usual way, and that some of the papers would have been improved if they had been subject to the normal refereeing processes. This is not to deny the value of the conference, which evidently succeeded in bringing together people with a variety of interests and, so participants inform me, was both interesting and enjoyable. A. J. M. SPENCER

MANY-BODY THEORY

Field Theoretical Methods in Many-Body Systems By D. A. Kirzhnits. Translated by A. J. Meadows. Edited by D. M. Brink. (International Series of Monographs in Natural Philosophy, Vol. 8.) Pp. xvi+394. (Oxford, London and New York: Pergamon Press, Ltd., 1967.) 110s. net.

This book was published in Russian in 1963. The author has not attempted to give a comprehensive survey of many-body systems, but has shown in detail how methods developed originally for problems in the quantum theory of fields can be used to get systematic approximations for many-fermion systems such as nuclei, atoms and plasmas. Most of the book is concerned with the properties of the ground state and low lying excited states of such systems, but there is a short final chapter on the use of these methods at non-zero temperatures.

In many treatments of many-body theory approximations such as Hartree-Fock theory, the random phase approximation or Brueckner theory is introduced by using arguments the range of validity of which is far from obvious. Kirzhnits restricts his attention to systems in which certain parameters are small, and uses perturbation theory to obtain systematic expansions in these small parameters. He considers, for example, systems with forces of a very short range, very weak long-range forces, and systems the density of which varies very slowly in space. The difficulty with this approach is that for real systems these parameters are not small enough to be sure that the approximation is good. The table of results on page 182, calculated for nuclear masses and shapes, is very much more impressive than anything that has been obtained by using Brueckner theory, and might justify the dismissal of Brueckner's method as "highly complicated, requiring very extensive numerical calculations". There is, however, no indication of the sensitivity of the results to the form of the interaction between the nucleons

which is assumed. If the calculations based on Brueckner theory are correct, the results are so sensitive to the form of the interaction that the good agreement with experiment must be regarded as a coincidence.

The book is not easy reading, but contains a systematic development of a particular approach to many-fermion problems, and is a valuable addition to the literature.

D. J. THOULESS

RAMAN SPECTROSCOPY

Raman Spectroscopy
Theory and Practice. Edited by Herman A. Szymanski. Pp. ix + 255. (New York: Plenum Press, 1967.) \$12.50.

This book consists of seven review articles on particular aspects of Raman spectroscopy by specialists in certain fields. A general introduction by L. A. Woodward is designed to give an account of the theory of the Raman effect and to indicate the types of application in which it has been found to be of value. This is very well done, but the treatment of symmetry properties in the nomenclature of group theory is so terse that it might prove a deterrent to further study rather than the stimulant intended. Chapters by J. R. Ferraro and by J. A. Koningstein describe respectively modern Raman instrumentation and techniques (using commercial instruments in the main) and the application of lasers to Raman spectro-A fairly detailed account of the relationships between Raman intensities and the derivatives of bond polarizabilities is given by R. E. Hester. J. Behringer describes the problems associated with observations of Raman scattering of light close in wavelength to absorption features (resonance Raman scattering). the scattering is very strong in these conditions the interpretation of the observations can be more difficult than in normal Raman scattering.

The remaining chapters deal with the more specific problems of ionic melts (G. J. Janz and S. C. Wait, jun.) and complex ions in solution (D. E. Irish). They provide interesting examples of the scope of Raman spectroscopy and both include a brief but clear discussion of

some selection rules in group theoretical terms.

This is a rather patchy book, but nevertheless interesting and should be of particular value to those with some experience in general spectroscopy.

D. W. O. HEDDLE

SEMICONDUCTORS

Semiconductors and Semimetals

Edited by R. K. Willardson and Albert C. Beer. Vol. 1: Physics of III-V Compounds. Pp. xii + 500. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 152s.

This is the first of a series of volumes to be devoted to the physics of semiconductors and semimetals. The first three volumes of the series review the properties of III-V compounds, and this first volume is concerned particularly with band structure, magnetic field phenomena and plasma effects in the III-V compounds.

The authors have attempted to provide a reference work which combines a review of material already available, together with a substantial proportion of new material. Thirteen authors contribute to this volume, which begins with an introductory chapter by C. Hilsum, who provides a clear and concise outline of the present status of work on III-V materials.

The following chapters are grouped under the three headings of "Band Structure", "Magnetic Field Effects"

and "Plasma Effects". Two chapters are devoted to methods of band calculation for III-V compounds, and these underline the difficulty of the analytic approach in determining data on band structure which can be compared with experimental results. Much useful general information on band shapes can, however, be derived. The rest of the section on band structure deals with effects of heavy doping, which is becoming of increasing importance in the design and understanding of many experimental devices, and on the band structure of alloys, in particular the variation of band gap with composition.

The section on magnetic field effects includes two chapters on magnetoresistance, outlining the use of this phenomenon as a diagnostic tool in examining band characteristics and conduction mechanisms. The chapter by Becker includes a useful survey of results on a range of III-V compounds.

The final chapter describes plasma effects in III-V compounds, including a survey of equilibrium plasma effects undertaken to determine band parameters, and a description of the difficult area of non-equilibrium plasma investigation.

This volume seems to me to achieve its aim to be a comprehensive reference work for the specialist working in the field of III-V compounds. It is not appropriate as an introduction to the physics of these compounds, however, and, as such, its suitability for graduate courses is questionable. It is clearly very difficult to combine separate contributions from many authors, and although the editors have selected authoritative articles to include in the book, it remains a collection of separate articles rather than a cohesive whole. Nevertheless, it is obviously the most complete survey of the physics of III-V compounds which has appeared so A. A. SHEPHERD

UNIFIED MACHINES

The Unified Theory of Electrical Machines By Charles V. Jones. Pp. x+542. (London: Butterworth and Co. (Publishers), Ltd., 1967.) 90s.

ELECTRICAL machines, as a subject, is perhaps not as much "out of fashion" at the present time as the authorsuggests in his preface. Indeed, one might argue that the particular aspect which is the subject of the suggests in his preface. whole book has become very much more fashionable duringthe past few years and the author need have no fears that his book will seldom see the light of day, for it is an excellent treatise which is certain to be read with enthusiasm by generations of students who are interested in electric motors and generators.

One of its main attractions is that the student needs so little in the way of background knowledge before he can begin to read it intelligently. The author spells out every step carefully, never accelerating too rapidly over what many authors might consider too well trodden ground, and yet progressing in depth into the subject, certainly up to degree finals standard. It is clearly written by a practising engineer and cannot be criticized as the work of an abstract academic. The arguments used to develop the subject are both logical and persuasive and many of those hitherto prejudiced against generalized theory cannot fail to be converted.

The book is unusual in that many sets of experimental results are quoted in support of the theory, as might be the case with a paper in proceedings of learned societies. or in technical reports, and this is refreshing in a textbook. It might even be said that it needs courage to include material of this kind, as could also be said of paragraphs. when the author gives a brief account of his own thought processes leading to particular developments. It is a great pity that more standard textbooks are not written in this attractive style.

Although originally intended for final year undergraduates, much of the material could be absorbed by second year students and would form an excellent introduction to third year studies, because the material is so clearly presented. The author suggests sections of the book which might be used as a short course.

E. R. LAITHWAITE

ELECTRICAL TEXT

Electrical Technology

By Edward Hughes. Third edition Pp. xvii+709. (London: Longmans, Green and Co., Ltd., 1967.) 25s. paper; 35s. cased.

Ir is difficult to say immediately why Electrical Technology should be a depressing book. The exposition is lucid, the printing and layout clear, and although in a book of this size there must be some misprints they are not obvious. The selection of questions, too, is exactly right for passing the examinations of the Ordinary National Certificate. Perhaps it is the line drawings which make it look older than its first edition of 1960. Marconi himself would have recognized the valve on page 517, and the drawings in general have an Edwardian look. But, of course, blocks are expensive to make and the book is good value at 35s. Any book aimed at a particular examination has the limitations of the syllabus and, though this has recently been changed (hence this third edition), it remains out of date. Although it is nice to see an electronics section, thermionic valves play too big a part, while the transistor section is rudimentary and there is no hint of digital methods. Authors have no control over the syllabus of the examinations for which their books are used, and publishers often feel that extraneous material adds to the printing cost without enhancing sales. I wonder whether the omission of current research work, such as that on linear motors or direct current machines without commutators, really diminishes the cost of a book by a significant amount. Its omission deprives the inquiring student of a sense of progress and excitement in his L. MOLYNEUX subject.

HETEROCYCLIC ADVANCES

Advances in Heterocyclic Chemistry, Vol. 7 Edited by A. R. Katritzky and A. J. Boulton. Pp. xiv+511. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 176s.

Advances in Heterocyclic Chemistry, Vol. 8 Edited by A. R. Katritzky and A. J. Boulton. Pp. xiv+404. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.) 152s.

THE latest two volumes of this semi-annual publication fully maintain the standards established during the past four years, with a selection of timely reviews on both general and specialist aspects of the subject. No one, however Philistine, can fail to find interest in at least some of the material, while to the research worker active in heterocyclic chemistry this series must be an important part of his library.

The seventh volume includes an invaluable and comprehensive review of more recent aspects of the chemistry of furans, tailored to act as a supplement to existing publications. The mass spectrometry of simple heterocycles is also summarized briefly in a chapter which is mainly devoted to the mass spectra of alkaloids. Methods available for the halogenation of heterocycles are discussed

in practical as well as mechanistic terms and the influence of reaction conditions, catalysts or modern halogenating reagents on the orientation of the product is summarized in tabular form. The mechanistic complexities of the process are also underlined.

Not the least attractive contribution to this volume is a review of reviews on heterocyclic systems. This systematic compilation of references to recent books, reviews and articles spans the entire range of heterocycles together with related natural products, drugs and pigments. This most valuable source of information will be widely used and widely appreciated. Of less general interest are chapters on diquinolyl-methanes, a "recent advances" review of 1,3,4-oxadiazole chemistry and an extensive account of the chemical and spectroscopic features of the quasi-aromatic 1,2 and 1,3-dithiolium salts.

On the whole, the eighth volume in the series will be appreciated by specialists more than by general readers. A chapter on the formation and behaviour of cyclic peroxides (which are formally heterocycles) includes the process of ozonolysis, and will be of more general interest. I was also captivated by an exhaustive survey of thio-, thia- and thio-thia-pyrones (α and β) which reviews their preparation and properties (chemical and spectroscopic) and the inter-relation of structure and properties. Equally interesting and equally comprehensive is an account of the chemistry of indoxazenes and anthranils, that is, the benzo-analogues of isoxazole. This volume also contains shorter reviews of the Claisen rearrangement in N-heterocycles, heterocyclic diazo-compounds and the Hilbert-Johnson reaction. The fundamental chemistry of the phenoxazine nucleus, the parent system of the actinomycin antibiotics, is also reviewed, and a thorough painstaking survey of 1,2, 1,3 and 1,4-diazepines provides the first English account of these systems.

G. L. BUCHANAN

ROTATORY DISPERSION IN BONN

Optical Rotatory Dispersion and Circular Dichroism in Organic Chemistry

Including Applications from Inorganic Chemistry and Biochemistry. (Proceedings of a NATO Summer School held at Bonn, 24 Sept.-1 Oct., 1965.) Pp. xvi+416. (London: Heyden and Son, Ltd., 1967. Distributed in the USA by Sadtler Research Laboratories, Inc., Philadelphia.) 96s.; \$13.50.

In the summer of 1965 Dr Günther Snatzke organized a NATO Summer School at Bonn on optical rotatory dispersion and circular dichroism. The present handsome volume, which he edited, emerges as a substantial result of a most enjoyable meeting. There are seventeen contributors and twenty-three chapters and, happily, the intermittent maelstrom of discussion has not been put on permanent record.

One of the aims of the meeting was to introduce the subject matter to chemists unfamiliar with it. Its success in this respect is reflected in the proceedings, a notable achievement being the variety of approaches, summed up by experts in the field, offered to the student. Moreover, the treatment is balanced in the sense that, although the bulk of the material refers to organic chemistry, there are substantial sections on inorganic and biological aspects. After general introductory chapters by P. Crabbé and by C. Djerassi, the theoretical background is outlined first by A. Moscowitz and then by S. F. Mason, who also has a chapter on inorganic applications. So, too, does F. Woldbye who, for his second barrel, has a useful section on instrumentation. Several contributors discuss the relative merits of ORD and CD, and P. Crabbé devotes a chapter to this: not surprisingly, it is best to have both facilities. But overall one gets the impressionwhich has become stronger rather than otherwise in the intervening two years—that, given equal coverage of the spectrum, then CD has a decided edge on its competitor, especially in dealing with complicated chromophores.

As usual, the carbonyl chromophore comes in for a lot of attention (saturated compounds—W. Klyne; unsaturated ketones—G. Snatzke; carboxylic acids, lactones, lactams—W. Klyne, H. Wolf), but, in addition, a wide variety of chromophoric derivatives of "colourless" substrates are discussed (B. Sjöberg) and there are sections on sulphur compounds (K. Kuriyama) and twisted conjugated systems (K. Mislow).

Temperature and solvent effects are not well understood in detail, but are important because they may tax structural correlations. The editor has a chapter on the former, while solvation studies are discussed by A. Rassat and A. Moscowitz. A section by J. Badoz on magnetically induced optical activity is particularly interesting because, unlike many of the other topics in this volume, this is not given much prominence in standard texts. The possibility of using this effect, discovered by Faraday in 1845, to obtain useful information about optically inactive molecules is an intriguing one, but, from what has appeared so far, it seems that progress has been rather slow. Badoz remains stoical about this, and studies are evidently continuing.

The general impression left by this volume is favour-Two criticisms should be made, however. first is that the proceedings appear about two years after the conference: to my mind it seems better that proceedings, if published at all, should be produced rapidly and treated as ephemera, the substance of the material appearing in permanent form in the established journals. The present volume is somewhat unusual, of course, in its pedagogic intention: it has evidently been carefully produced—which takes time—and, in places, supplemented since the meeting. One is left wondering, however, whether the re-publication, practically word for word, of papers already in the literature is defensible in this context. Portions of no less than six chapters are reproduced from journals, and one chapter appears to be almost entirely composed in this way. It is to be hoped that this practice will not catch on: both the student and the library deserve a better deal. R. BONNETT

STUDENT MICROBIOLOGY

The Biology of Fungi, Bacteria and Viruses

By Greta Stevenson. (Contemporary Biology.) Pp. xiii+202. (London: Edward Arnold (Publishers), Ltd., 1967.) 42s. net, boards; 21s. net, paper.

This comparatively short book, intended for first year students, covers a wide range, though perhaps rather less wide than the title suggests. By far the greatest emphasis is on fungi, with bacteria given much less space and the viruses being little more than mentioned. The book is divided into three main sections: "Cell Organization and Physiology", "Special Habitats and Economic Aspects", and "Diversity of Fungi in Relation to Environment".

The first section is perhaps the least satisfactory. So far as the fungi are concerned the account of cell organization is not very clearly distinct from the themes of the last section, and the account of the organization of bacterial cells is brief and superficial. The chapter on metabolism outlines a number of metabolic pathways and says something about macromolecules, not always accurately. For example, on page 31 acetaldehyde is said to combine with oxaloacetate to form citrate in the tricarboxylic acid cycle, on page 43 ribosomal RNA is not mentioned when the main classes of RNA are being listed, while, on the following page, a relationship between amino-acid and tRNA anti-codon is implied which is, to say the least, not generally accepted as true. This part

of the book may be useful for quick reference but cannot be recommended for students who have no biochemistry text against which to check their facts.

The second section is somewhat discursive, dealing with such varied topics as soils, the biology of water supplies and plant and animal pathology. In the available space there is room for only a few examples, and others would no doubt have placed the emphasis differently. I felt that the section on soils was given more weight than was warranted by its microbiological content. However, this attempt to place micro-organisms in their proper biological contexts is refreshing and should catch the interest of students.

The most solid and conventional but at the same time probably the most valuable section is the last. Here is a brief but comprehensive guide to the main fungal groups with a summary of their system of classification. For those who do not need to pursue mycology to the extent of buying a specialized text, this section provides a brief but adequate account of the fungi. Another feature which will be very useful for students is the table showing comparative sizes of various microbiological and molecular objects.

In summary, Dr Stevenson has written an original book which, although not outstandingly successful in all respects, should prove useful to many of the students at whom it was aimed.

J. R. S. FINCHAM

WORK WITH TISSUES

Animal Tissue Techniques

By Gretchen L. Humanson. Second edition. (A Series of Books in Biology.) Pp. xvi+569. (Sin Francisco and London: W. H. Freeman and Company, 1967.) \$9.00; 72s. net.

It would not be fair to describe this book as just another manual of histological techniques; it aims to explain the basis and application of the techniques rather than simply to present a list of favourite recipes. It contains sections on histochemistry and autoradiography, on exfoliative cytology, on the preparation of invertebrates for whole mounts and sections; and the student is introduced, briefly, to electron microscopy and immunofluorescence techniques. But it certainly does not contain anything which tissue culturists, cell biologists or experimental pathologists might expect to find in a book bearing this title, nor is the author attempting to cater for them.

The opening section, on fixation, dehydration, embedding, sectioning and staining of tissues, contains well illustrated accounts of the cutting of paraffin sections and the sharpening of microtome knives, but the chapter on the use of the microscope is not illustrated and the descriptions are barely adequate. The following section on the staining of tissues, with sub-sections on the staining of intracellular organelles and micro-organisms and on vital staining, contains a wealth of detail and references. There is a useful closing section on solution preparation and general laboratory aids. Some of the materials are referred to by their trade names, although the composition of the product is usually indicated. Readers outside the United States, when they are not able to purchase similar products locally, will wish that the addresses of the suppliers of apparatus and materials referred to in the footnotes were given more fully.

In her incidental comments the author occasionally seems out of her depth. We are informed, in the opening sentences of the book, that during autolysis intracellular enzymes "appear to reverse their action; instead of synthesizing amino acids into cell proteins, they begin to split proteins into amino acids", and later (page 231) that lymphoblasts produce monocytes, plasma cells and lymphocytes. The remarks in the section on antigenantibodies which introduces the Coon's fluorescent

antibody technique are equally naive: "...If the fluid portion of blood plasma is allowed to clot (fibrinogen precipitates out), or a relatively stable serum remains. This is made up of two protein fractions: albumin and globulin. The globulins consist of two alpha globulins, one beta globulin and one gamma globulin..." The author seems to have included these comments as a matter of policy without giving them much thought; her real interest appears to be in the methods themselves and it is easy to believe that she has had personal experience of most of them.

N. R. Ling Norman Williamson

TEACHING PLANT PATHOLOGY

Sourcebook of Laboratory Exercises in Plant Pathology (Sourcebook Committee of the American Phytopathological Society.) Pp. xxvii+388. (San Francisco and London: W. H. Freeman and Company, 1967.) 68s.

THE material in this book has been assembled in its present form by members of the American Phytopathological Society with the intention of encouraging a more experimental approach to the teaching of plant pathology. The method chosen to achieve this aim has been to set down in detail a series of laboratory exercises in the hope that individual teachers may find at least some of the ideas pertinent to their particular courses.

The experiments cover all the major activities of the fungi, bacteria, viruses and nematodes in relation to plant pathology, while the standard of the exercises ranges from the straightforward isolation of fungi from the soil through to advanced research procedures only suitable for demonstrations. Some of the experiments will no doubt make interesting and worthwhile additions to specialist courses in this subject, and the descriptions of the techniques employed are, on the whole, lucid and informative. The very clarity of the text, however, is sometimes deceptive and many of the apparently "simple" exercises may well prove more difficult than indicated when executed by students not too familiar with the handling of micro-organisms. This possible drawback is enhanced by the fact that no real indication is given as to how skilled an experimenter needs to be in order to obtain the suggested results, and because many of the techniques are intended as innovations to general laboratory work, this lack of guidance may well lead to some disillusionment among those tempted to abandon familiar pathways.

The overall approach adopted in this book is, in many ways, rather disappointing, for the editors seem to have ignored the basic problem that they set out to solve, namely, "how the descriptive and taxonomic approach to the teaching of plant pathology may be integrated with the more dynamic aspects of the science". Thus, in compiling these exercises, those involved seem to have been thinking solely in terms of what should theoretically be included in a plant pathology course in ideal conditions, rather than concentrating on how the basic facets of the subject could be brought to life. For this reason it seems doubtful whether this book will go very far towards achieving its aims, whereas had the committee responsible for its production been content to influence a smaller audience, with the emphasis on enlivening and expanding the type of experiments suited to a particular group, then the book would probably have more impact. As it stands, with an apparent potential readership from high school children through to postgraduate research workers, it has simply become a collection of experimental techniques, and a potentially exciting project appears to have completely lost steerage through a failure to adhere to better defined R. K. Robinson parameters.

INSIDE PLANTS

Plant Anatomy

By A. Fahn. Translated from the Hebrew by Sybil Broido-Altman. -Pp. viii+534. (Oxford, London and New York: Pergamon Press, Ltd., 1967.) 75s. net.

This book by the professor of botany at the Hebrew University of Jerusalem is an English translation of the Hebrew edition. It is intended as a general and comprehensive introduction to plant anatomy and as such it is conventional in plan. The book begins with a consideration of the cell; has chapters on meristems, tissues, the primary and the secondary plant body, and concludes with three chapters on reproductive organs.

Any text book on plant anatomy must deal with a vast quantity of facts and, perhaps inevitably, mistakes will occur. This book is no exception. For example, parenchyma is not always composed of living cells as is implied on page 73, neither is all collenchyma formed in the way described on page 80. The statement on page 273 "that in woody . . . [plants] . . . the primary tissues of the stem and root exist for a relatively short period before they become destroyed or obliterated by the development of the secondary vascular tissue . . ." is not only wrong and misleading but suggests some misunderstanding of

the process of secondary thickening.

On page 292 it is stated that resin ducts occur in the secondary xylem of Abies and Cedrus, two genera in which resin ducts do not normally occur although occasionally traumatic ducts may be found, more particularly in Cedrus, and it is these abnormal ducts which are illustrated in Fig. 128.2.

There is in many places a lack of precision in the writing and in many instances statements on the same topic in different places are not consistent; for example, xylem as defined on page 102 and subsequent descriptions of this tissue. There are other examples and it may be that these are, at least in part, the results of the problems of translation.

An undergraduate student using this book will learn many facts about plant anatomy, but I doubt whether such a student will obtain an integrated picture of the structure of a living plant. Perhaps the author has tried to include too many facts so that it has become difficult to see the wood for the trees.

The book is copiously illustrated, but the illustrations vary in quality. The line diagrams are generally clear but the same cannot be said for all the micrographs. The student is likely to find Fig. 117 or Fig. 120.2 difficult to interpret.

Most of the genera, if not all the species, of plants referred to will be familiar to students in this country. The book has a glossary, and is provided with both an author and a subject index.

D. J. B. White

EXPERIMENTAL ANIMAL ECOLOGY

Introduction to Experimental Ecology

By T. Lewis and L. R. Taylor. Pp. xi+401. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1967.) 37s. 6d.; \$6.50.

As a university teacher who is continually faced with first year students completely lacking any previous practical ecological experience at the school level, it was with considerable pleasure that I read *Introduction to Experimental Ecology*.

It is obvious a considerable amount of work and careful selection of material has gone into the preparation of this book. The exercises are chosen from a wide range of habitats, which makes the book equally valuable to schools situated in towns as well as the more fortunate rural ones. The statistical treatment of the data has been

explained in a clear and lucid fashion and the maximum information extracted by use of simple techniques.

Both the authors and publishers are to be congratulated on an excellent book—the only serious criticism I make is the title, which should read "Introduction to Experimental Animal Ecology".

K. A. Kershaw

PEEPHOLES INTO COGNITION

Concepts and the Structure of Memory

Edited by Benjamin Kleinmuntz. (Carnegie Series on Cognition.) Pp. xiv+286. (New York and London: John Wiley and Sons, 1967.) 64s.

The psychology department at the Carnegie Institute of Technology has collected funds from a variety of sources in order to promote annual symposia on various aspects of cognition. The proceedings of the brief meetings together with prepared comments on the papers are published in hardback book form. The present volume results from the second symposium of the series. It consists of seven original contributions, four on concept attainment, three on memory, comments on these taken in pairs (one escapes) and an "overview" by Newell and Simon.

Whereas the title, by including the archaic term "structure of memory", carries overtones of mentalistic psychology of the nineteenth century, the book actually provides glimpses of current research projects. With the exception of Hunt's paper on the computer simulation of concept formation, all deal with the molar behaviour of normal human subjects in the tradition of modern experimental psychology.

The papers on concept learning are notable for the breadth of the interpretation the topic is given. Bourne shows how he is extending the development of the analysis of traditional concept attainment tasks and procedures which was initiated by Bruner, Goodnow and Austin. While, by contrast, Martin adopts the position of an extremist S-R theorist: "...all behavior is caused, that is ... every response has a stimulus". His employment of S-R theory is novel, however, for he stresses the significance of responses which are inhibited in any particular situation. His field of application is also novel, for he argues that multiple choice reaction time experiments can properly be regarded as concept learning tasks.

The contributions on memory are unexciting by comparison. The main theme is the retrieval process. Peterson's thesis is that it can be separated into search and decision components, while Cofer predictably examines clustering as an example of conceptual organization. Surprisingly, he finds that it does not generally result in augmented recall.

These comments on the content should make it clear that this book is intended for the initiated. It is primarily of interest to researchers in these two fields for whom the informal presentation of work which is in its preliminary stages will be especially fascinating. As an attempt to bring two research areas together the exercise has largely failed. There are obvious points of contact between concept learning and memory, and many contributors have mentioned them. In the main, however, after briefly pointing to the relevance of their work to those in the other field, they have then proceeded with an exposition of their own favourite topic. If the conference was aimed at cross fertilization, then the progeny are yet awaited. And this admixture reduces the appeal of the book. It would be more useful if it had provided a wider sample of contributions on a single topic.

A general point is that books of this kind can serve a useful purpose. Their publication lag is less than that of many journals and the preparation lag is obviously considerably shorter. They therefore speed up communication in science. But they are only of interest to the

specialist and are only of passing interest at that. Why then are they not published as paperbacks at a fraction of the price?

H. C. A. Dale

OBITUARIES

Dr J. C. Trevor

J. C. Trevor, who died in July, aged 59, had a considerable reputation as a physical anthropologist in Great Britain and abroad. He had a wide knowledge and was particularly interested in the history of the subject. His special interests were race mixture, the physical history of man in Africa and the British Isles, and the anthropology of New World Negroes. He was something of a perfectionist, both concerning the collection of his data and in the way in which he wrote about them, and this probably accounts for the relatively small number of his publications. He could not bear to publish what he considered to be a shoddy piece of work and was untiring in his efforts to encourage his pupils to be accurate in their work and elegant in their writing.

Almost all of his work was based on biometric methods

Almost all of his work was based on biometric methods and his articles in *Chambers's Encyclopaedia* and the *Encyclopaedia Hebraica* on anthropometry and race express concisely Trevor's view of his special interests in

physical anthropology.

Before the war he published several papers, the most interesting being "Some Anthropological Characteristics of Hybrid Populations", which was followed in 1953 by "Race Crossing in Man: the Analysis of Metrical Characters". Professor L. S. Penrose, writing in the introduction to the latter, says: "It summarizes information which can never be out of date. As a contribution to both human genetics and physical anthropology it falls naturally into place as a Eugenics Laboratory Memoir. This series . . . was started by Karl Pearson in 1907 and has been continued ever since". These comments seem to be as valid today as they were in 1953.

Trevor's interest in the history of man in Britain ("The Rough Island Story", as he often called it) is reflected in papers in *Biometrika* and in his Monroc Lectures to the University of Edinburgh in 1952 on "The

Racial History of Britain".

His childhood and war service in Africa certainly gave Trevor an interest in the racial history of that continent. His 1949 paper on "The Physical Characteristics of the Sandawe" in the Journal of the Royal Anthropological Institute is a good example of his thorough anthropometric and anthroposcopic work and careful statistical analysis of the results. The Ancient Inhabitants of Jebel Moya (with R. Mukherjee and C. R. Rao) is another massive contribution to the racial history of the northeastern part of the African continent.

Lastly, there remain a group of publications like his contributions to Simpson's Modern Trends in Forensic Medicine, "The Fontechevade Skulls and the Origin of Homo sapiens" (Nature, 1959), "Oreopithecus bambolii" (Antiquity, 1959), which reflect Trevor's wide interest and very considerable knowledge of physical anthropology.

He used to say that neither biometric methods nor the "trained-eye" methods were valuable by themselves. He always maintained that when studying primate osteological material one should remove subjectivity as much as possible, but that nevertheless a trained eye could see much that measurements might overlook. In consequence, he advised the use of both techniques.

Some may feel that Jack Trevor's kind of anthropology has become a little outmoded, but certainly his professional integrity and high standards are manifest in his publications and could well be emulated by any beginner in the field.

MARIE LAWRENCE

CORRESPONDENCE

Special Relativity

Sir,—I refer to Professor Dingle's paper on "The Case

Against Special Relativity" (Nature, 216, 119; 1967). It is, I think, implicit in Professor Dingle's argument that equation (3) is derived by an observer at rest in the AH frame who initially synchronizes A, B and H to zero but not N. He later, again at rest at H in the AHframe, reads B and H when they are adjacent. He thus determines the ratio of the rates of clock A to clock B from the point of view of an observer at rest in the AH

It is similarly implicit that equation (4) is derived by an observer at rest in the NB frame who initially synchronizes NB and A to zero but not H. Later at rest at N in the NB frame he reads N and A when they are adjacent. He thus again determines the ratio of the rates of clock A to clock B but this time from the point of view of an observer at rest in the NB frame.

It is entirely in accord with the principle of relativity that one of these ratios is the reciprocal of the other, for the clock which moves relative to the observer always goes slower. It does not alter the argument if one observer sets all the clocks and makes all the observations by accelerating back and forward between the two frames.

Yours faithfully,

J. H. FULLERTON

11 Purley Bury Avenue, Purley, Surrey.

SIR,—Without detracting from the completeness of Professor McCrea's reply to Professor Dingle, may I suggest a simple way of pointing the fallacy in the latter's argument?

Professor Dingle's rate-ratios (3) and (4) both purport to refer to the same observer A; (3) is correct, but (4) is false and is actually the rate-ratio as observed by B, for the following reasons. The following arguments can be levelled against it.

(i) The time-interval $(0, t_2) = (0, at_2)$ is an interval on A's clock-for any observer.

(ii) The time-interval $(0, t_2')$ is the difference between the reading "zero" on B's clock, and the reading t_2 on N's clock. For A, this difference is physically meaningless, since for A these two clocks are not synchronized. According to the theory, A observes a constant difference between their readings.

However, if the readings are regarded as observations by B, the intervals are valid, so that as stated before, formula (4) is the rate-ratio as observed by B and is, naturally, the reciprocal of that observed by A.

Yours faithfully,

W. BARRETT

Department of Mathematics, University of Leeds.

"Snags in Space"

SR,—Your conference report of October 21 (Nature, 216, 215; 1967) refers to certain difficulties which have arisen in decoding a fraction of the data from the scientific experiments on board the Ariel III satellite. The statements in your report arose from a discussion of these difficulties at a meeting which was concerned with the

apparatus rather than the scientific results, and which may therefore have given an unbalanced impression of the performance of the experiments as a whole. We wish to offer some corrections.

The first point is the reference, in the conference and in your report, to "interference" from the Birmingham experiments. This might be thought to be some type of spurious signal generated in the apparatus of the Birmingham electron density or electron temperature experiments, but in fact no such signals are present in the intended frequency bands of any of the seven high gain radio receivers associated with other experiments on board the satellite. What is observed instead is an unusual form of cross modulation, by way of the plasma sheaths surrounding the satellite and Birmingham experiment sensors. which appears to occur between the audio-frequency signals of the Birmingham experiments and the input stage of the Jodrell Bank galactic radio noise experiment.

If it had been anticipated in advance that such a cross modulation were likely to occur, it might have been avoided either by modifying the switching sequence programme of the Birmingham experiments or by changes to the input stages of the Jodrell instrument; but it is not profitable to speculate, after the event, on the possibility that the problems with which we are faced could have been avoided by more detailed consideration at the development stage. The cross modulation is a form not previously known and the knowledge we stand to gain relating to its exact mechanism will offset to some small extent any loss of expected data.

There are considerable periods when the effects of the ionospheric cross modulation are negligible. At these times we have been able to demonstrate the anticipated effect of the ionosphere on the cosmic radio background showing as a progressive reduction in radiation resistance of the loop antenna as the electron density increases. At the upper end of the frequency sweep, at 4.2 MHz, where the effects of the geomagnetic field are small, it is easy to show that the values of electron density measured by the Birmingham experiment are in close agreement with values obtained from measurements of the radiation resistance which must refer to ionosphere propagation conditions over a large volume in the vicinity of the This encourages us to believe that both spacecraft. experiments are working exactly as planned and that the radio astronomical experiment will fulfil at least part of its intended purpose.

Some misunderstanding must also have arisen concerning the Meteorological Office experiment. You state that "The Birmingham experiments have also upset the attempt by the Meteorological Office to measure the concentration of molecular oxygen in space". This is simply not true. There is a quite marginal amount of cross modulation present in the Meteorological Office data, but this can readily be allowed for in the analysis and does not significantly affect the quality of the measurements of molecular oxygen concentration.

J. SAYERS

University of Birmingham.

F. G. SMITH

Nuffield Radio Astronomy Laboratories, Jodrell Bank.

K. H. STEWART

Meteorological Office, Bracknell.

This account is substantially in agreement with that published in Nature two weeks ago. The term "interference" is that used in the abstracts circulated at the meeting. The report also described the interference with the Meteorological Office experiment as "not too severe", but it is good to know that even that was an exaggeration. Editor, Nature.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 6

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 1.15 p.m.-Professor Ronald King: "Faraday—Father of Electrical Engineering".

FARADAY SOCIETY (in the Department of Chemistry, The University Edinburgh), at 4.30 p.m.—Professor Dudley Herschbach (Harvard University): "Molecular Beam Kinetics" (Bourke Lecture).*

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Lecture on "AC and DC Current Comparators".

INSTITUTION OF MECHANICAL ENGINEERS, NUCLEAR ENERGY GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "What Can We Do Without in a Nuclear Power Station?".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, WC2), at 6.30 p.m.—Mr F. F. Mazda: "Thyristor Control".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, SW1), at 6.30 p.m.—Dr M. W. Davies: "The Chemistry of Iron and Steel Making".

Tuesday, November 7

FARADAY SOCIETY (in Lecture Theatre No. 4, School of Chemistry, The University, Bristol), at 4.30 p.m.—Professor Dudley Herschbach (Harvard University): "Molecular Beam Kinetics" (Bourke Lecture).*

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP—PHYSICOCHEMICAL AND BIOPHYSICAL PANEL (at 14 Belgrave Square, London, SW1), at 5 p.m.—Dr W. P. Anderson: "Free Space in the Plant Leaf".

UNIVERSITY OF LONDON (at the Royal Veterinary College, Royal College Street, London, NW1), at 5 p.m.—Dr C. R. W. Spedding: "Intensive Sheep Production from Pasture"."

Institution of Electrical Engineers (at Savoy Place, London, WC2), at 5.30 p.m.—Dr B. DeLisle: "Functional Studies of the Cortex Using Microelectrodes".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Eccleston Hotel, Victoria, London, SW1), 5.30 p.m.—Mr T. Plant: "Role of Specifications in the Rubber Industry". 7 p.m.—Mr J. A. Stephens: "Design and Application of Seals".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 5.30 p.m.—Sir Lawrence Bragg, FRS: "Waves and Vibrations". (Lecture for Sixth Form Boys and Girls from Schools in London and the Home Counties. To be repeated on November 8, 14 and 15.)

UNIVERSITY OF LONDON (at the Institute of Child Health, Guilford Street, London, WC1), at 5.30 p.m.—Professor D. W. Smithers: "Clinical Research in Hodgkin's Disease". (Seventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)"

University of London Institute of Education (in the Beveridge Hall, Senate House, Malet Street, London, WC1), at 5.30 p.m.—Professor Doris M. Lee: "Perspectives in the Education of Teachers".*

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at West Ham College of Technology, Romford Road, London, E15), at 6.30 p.m.—Mr P. Cooke: "Microelectronics".

Wednesday, November 8

ROYAL INSTITUTION, HISTORY OF SCIENCE DISCUSSION GROUP (at 21 Albemarle Street, London, W1), at 1 p.m.—Professor A. R. Hall: "Galileo and the Science of Ballistics".

COLOUR GROUP (Great Britain) (in the Physics Department, Imperial College, London, SW7), at 2.30 p.m.—Meeting on "Phosphors". Dr P. W. Ranby: "Phosphors in Lamps and Cathode-ray Tubes"; Mr R. C. Marshman: "Phosphors in Postal Sorting".

PLASTICS INSTITUTE, POLYMER PROPERTIES DISCUSSION CIRCLE (at 11 Hobart Place, London, SW1), at 2.30 p.m.—Meeting on "Stress Cracking".

INSTITUTION OF MECHANICAL ENGINEERS, INTERNAL COMBUSTION ENGINES GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 4.30 p.m.—Meeting on "Exhaust and Inlet Silencing".

ROYAL INSTITUTION OF NAVAL ARCHITECTS (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, SW1), at 5 p.m.—Professor J. F. C. Conn and Mr A. M. Ferguson: "Results Obtained with a Series of Geometrically Similar Models"; Dr R. L. Towsin: "Viscous Drag from a Wake Survey—Measurements in the Wake of Lucy Ashton Model".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, WC2), at 6 p.m.—Mr J. N. White: "Farm Buildings Design and the Landscape".

UNIVERSITY OF LONDON (at the Institute of Neurology, National Hospital, Queen Square, London, WC1), at 6 p.m.—Dr J. Marshall and Dr J. R. A. Mitchell: "Cerebrovascular Disease—Clinical and Biochemical Aspects".*

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (joint meeting with IFST, at 14 Belgrave Square, London, SW1), at 6.15 p.m.—Mr J. H. V. Davies: "Codex Alimentarius".

SOCIETY OF ENVIRONMENTAL ENGINEERS, PACKAGING GROUP (at the Euston Tavern, 73 Euston Road, London, NW1), at 6.30 p.m.—Mr B. G. Toms: "The Road Transport Environment".

Wednesday, November 8-Friday, November 10

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS AND THE INSTITUTION of Electrical Engineers (at the Institution of Electrical Engineers, Savoy Place, London, WC2)—Conference on "MF, LF, and VLF Propagation".

Thursday, November 9

INSTITUTION OF MECHANICAL ENGINEERS, MANUFACTURE AND MANAGEMENT GROUP (at 1 Birdcage Walk, Westminster, London, SW1)—All-day Meeting on "Management of Quality".

University of London (in the Anatomy Theatre, University College London, Gower Street, London, WC1), at 1.20 p.m.—Dr W. A. Smeaton "Science in the Capital of Burgundy: The Dijon Academy, 1740-1793".*

GEOLOGICAL SOCIETY, VOLCANIC STUDIES GROUP (at Burlington House. Piccadilly, London, W1), at 2 p.m.—Meeting on "Major Volcanic Structures".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 2.30 p.m. Professor E. R. Laithwaite: "Analogy—The Art of the Engineer" (Ci Service Lecture).

FARADAY SOCIETY (in the Chemistry Department (Faculty of Science), The University, Manchester), at 4 p.m.—Professor Dudley Herschbach (Harvard University): "Molecular Beam Kinetics" (Bourke Lecture).*

ROYAL SOCIETY (at 6 Carlton House Terrace, London, SW1), at 4.30 p.m.— Professor J. Baddiley, FRS: "Teichoic Acids and the Molecular Structure of Bacterial Walls" (The Leeuwenhoek Lecture).

UNIVERSITY COLLEGE LONDON (in the Galton Theatre, Gower Street, London, WC1), at 5 p.m.—Mr E. D. Brown: "The Lessons of the Torrey Canyon".*

UNIVERSITY OF LONDON (in the Physics Lecture Theatre, Westfield College, Kidderpore Avenue, London, NW3), at 5.15 p.m.—Professor D. R. Hughes: "The Uses of Mathematics".*

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W1), at 5.30 p.m.—Mr J. Lutoslawski: "The Polish Oil Industry".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr H. Goldenberg: "Transient Heating of Buried Power Cables".

UNIVERSITY OF LONDON (at the Institute of Child Health, Guilford Street, London, WC1), at 5.30 p.m.—Dr J. L. Turk: "The Cell Mediated Immunological Response". (Eighth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

Friday, November 10

ASSOCIATION OF APPLIED BIOLOGISTS (at the Royal Society of Arts, John Adam Street, Adelphi, London, WC2), at 11 a.m.—Symposium on "Wild Mammals and Their Control".

ROYAL INSTITUTION, PHOTOCHEMISTRY DISCUSSION GROUP (at 21 Albemaric Street, London, W1), at 1 p.m.—Dr B. Ward: "The Reactions of Hydrogen Atoms with Benzene and Toluene".

ROYAL INSTITUTE OF CHEMISTRY (at Birkbeck College, Malet Street, London, WC1), at 5.30 p.m.—Dr D. H. Williams: "Some Aspects of the Mass Spectra of Organic Compounds" (Meldola Medal Lecture).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 9 p.m.—Dr C. A. Wright: "The Island of Aldabra".

Monday, November 13

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the Electron Microscopy Group of the Institute of Physics and the Physical Society, at the Institution of Electrical Engineers, Savoy Place, London, WC2), at 10 a.m.—Colloquium on "Electron Probe Instrumentation".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, SW1), at 5 p.m.—Dr M. Elliott: "Structural Requirements for Pyrethrin-like Activity".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Dr A. R. W. Broadway and Mr G. Thomas: "Single-Unit P.A.M. Induction Frequency Convertors".

INSTITUTION OF MECHANICAL ENGINEERS, THERMODYNAMICS AND FLUID MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "The Transport of Solids by Gases".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the

dates mentioned:
SENIOR LECTURER (with qualifications in a branch of science or technology SENIOR LECTURER (with qualifications in a branch of science at postdoctoral SENIOR LECTURER (with qualifications in a branch of science or technology together with relevant academic or industrial experience at postdoctoral level) in the DIVISION OF MATERIALS AND MODECULAR SCIENCE—Clerk to the Governing Body, Woolwich Polytechnic, Wellington Street, London. SE18 (November 14).

RESEARCH ASSISTANT IN CANCER ENZYMOLOGY—The Registrar, The University, Liverpool, quoting Ref. RV/218/N (November 15).

TUTORIAL RESEARCH STUDENT (graduate) IN PHYSIOLOGY—The Secretary, Bedford College (University of London), Regent's Park, London, NW1 (November 16).

(November 16).

EXPERIMENTAL OFFICER (with experience of instrument design or construction involving electronics or optics, and preferably experience in spc ctroscopy) in the DEPARTMENT OF CHEMISTRY—The Registrar, University of Manchester, Manchester, 132, quoting Ref. 162/67/Na (November 18).

LECTURER IN PHYSICS—The Principal, Bede College, Durham (November 18).

Manchester, Manchester, 13, quoting Ref. 162/67/Na (November 18).

Lecturer in Physics—The Principal, Bede College, Durham (November 18).

Chair of Anatomy at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, SW7 (Hong Kong and London, November 24).

Regus Chair of Botany in the University of Glasgow—The Private Secretary, Secretary of State for Scotland, Room 507, St. Andrew's House, Ediburgh, 1 (November 24).

Temporary Lecturer (with a medical degree registrable in the State of Queensland, and preferably postgraduate experience of some five years' duration in a clinical and pathological discipline) in Pathology at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, SW1 (Brisbane and London, November 24).

Lecturer/Assistant Lecturer in Physiology at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, SW1 (Hong Kong and London, November 25).

Lecturer in Theoretical Chemistry—The Registrar, University Senate House, Bristol, 2 (November 30).

CHAIR OF PRYSIOLOGY at St. Mary's Hospital Medical School—The Academic Registrar, University of London, Senate House, London, WC1 (December 1).

(December 1).

LECTURER (graduate in agricultural, veterinary or rural science, with a higher degree in a field of animal husbandry) in ANIMAL MANAGEMENT in the DEPARTMENT OF ANIMAL HUSBANDRY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (Australia and London, December 8)

The Association of Commonwealth Universities (Branch Office), altriborough House, Pall Mail, London, SW1 (Australia and London, December 8).

SENIOR DEMONSTRATOR (with a B.Sc. honours degree, or equivalent, in geology) in the Department of Geology, University of Melbourne—The Registrar (Appointment & 57), University of Melbourne, Parkville, Victoria, 3052, Australia (December 15).

University Lecturer in Physical Anthropology in the Department of Archaeology and Anthropology, The University, Downing Street, Cambridge (December 15).

Lecturer (Sexior and Anthropology—Dr S. J. Tambiah, Secretary of the Appointments Committee of the Faculty of Archaeology and Anthropology, The University, Downing Street, Cambridge (December 15).

Lecturer (Sexior and Anthropology), The University, Downing Street, Cambridge (December 15).

Lecturer (Sexior and Anthropology), University, Clayton, Victoria 3168, Australia; or The Secretary-General, Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, SW1 (December 22).

Principal Lecturer in Polymer Physics; and an Instructor in Polymer Physics—Clerk to the Governors, National College of Rubber Technology, Northern Polytechnic, Holloway, London, Nr.

Research Assistant (with a degree in biochemistry and preferably experience with proteins or nucleic acids) to participate in work on mode of action of vitamin D—The Director, University of Cambridge and Medical Research Assistant (with a degree in microbiology or bacteriology, or in biology with training in microbiology, and preferably some training in bacterial genetics to carry out research into the genetics of resistance to antibiotics in bacteria—The Deputy Director, A.R.C. Unit of Animal Genetics, Institute of Animal Genetics, West Mains Road, Edinburgh, 9.

Scientific Assistant—The Deputy Director, A.R.C. Unit of Plant Physiology, Impertal College of Science and Technology, London, SW7.

At last a truly routine NivIR spectrometer w'th a new d' mension in stabilityresolution stability tl anks to our permanent magnet 'w'th the 100-year g arantee.

NMR as a matter of routine
—using Perkin-Elmer's new
Model R12 Spectrometer
—becomes a reality at last.
60 MHz proton spectra flow
from the R12 in rapid
succession without any
adjustment, for the R12 has
the stability you really need.
Perkin-Elmer—and only
Perkin-Elmer—make a
permanent magnet the
power-house of their NMR

Spectrometers. No power troubles, no service worries, unaltered by time and use, the permanent magnet also eliminates problems of resolution stability. What else does the R12 offer? Easy installation in your laboratory—it has a desk-standing console, 36" wide; straightforward operation—you can use it after only minutes of

instruction; accurate integration with baseline fluctuations eliminated; Perkin-Elmer's self-aligning flow-chart recording system; and this new model is only half the price of comparable instruments. Interested? Get details from Perkin-Elmer Limited, Beaconsfield, Bucks. (Telephone Beaconsfield 2571, Telex: 83257.)

APPOINTMENTS VACANT

VICTORIA UNIVERSITY OF WELLINGTON NEW ZEALAND

Applications are invited for the following ap-pointments, applications for which close on the dates shown in brackets:

LECTURESHIP IN BOTANY: The teaching will be primarily in Cytology and Genetics, but may include some participation in first year teaching in general Botany, and in other areas appropriate to the qualifications of the appointee. (November 30.)

(November 30.)

LECTURESHIP IN PHYSICAL GEO-GRAPHY: Applicants should have qualifications in either geomorphology with special interests in statistical methods, or bio-geography with special interest in ecology. Asian field experience would be an added advantage. (November 30.)

The salary scale for a Lecturer is from SNZ3,000 rising to SNZ4,400, with a bar at this point, then on recommendation to SNZ4,800. The initial salary will be determined according to the qualifications and experience of an appointee. Superannuation is available on the F.S.S.U. pattern. Approved fares to Wellington will be allowed for an appointee and his dependent family together with actual removal expenses within specified limits.

Further particulars and information as to the

Further particulars and information as to the method of application may be obtained from the Association of Commonwealth Universities (Branch Office), Mariborough House, Pall Mall, London, S.W.1. (1492)

FOURAH BAY COLLEGE UNIVERSITY OF SIERRA LEONE

UNIVERSITY OF SIERRA LEONE
Applications invited for (a) Lectureship or (b)
Senior Lectureship in Botany. Preference given
to applicants with interests in cyto-genetics, ccology, cryptogamic botany (bryophyte or pteridophyte) or flowering plant taxonomy. Salary: (a)
£1,200 to £2,370 per annum; (b) £2,275 to £2,700
per annum plus supplementation (normally tax
free) of £275 to £450 per annum for those designated under British Expatriates Supplementation
Scheme. F.S.S.U.; various allowances; family
passages.

Detailed applications (six copies), naming three referees by December 4, 1967, to Inter-University Council, 33 Bedford Place, London, W.C.1, from whom particulars are obtainable. (1479)

UNIVERSITY OF SURREY EXPERIMENTAL OFFICER DEPARTMENT OF MECHANICAL ENGINEERING

ENGINERING

Applications are invited from men aged 25 years and over to assist in experimental work in connection with an extensive investigation on turbine and compressor blade vibrations at high rotational speeds. This work is being conducted with the support of a grant from the Science Research Council. The successful applicant must have an H.N.C. or equivalent in the appropriate field, and at least two years experience in a similar research environment. The post will be for two years duration in the first instance. Salary at an appropriate point on the scale £1,250 by £50 to £1,650 plus £60 London Allowance.

The Department is scheduled to move to the new University site at Guildford in 1968. Substantial assistance will be given towards travelling expenses to staff travelling from the Guildford area whilst the University is in London.

Please apply to the Staff Officer, University of Surrey, Battersea Park Road, London, S.W.11, for an application form. (1490)

AUSTRALIAN ATOMIC **ENERGY COMMISSION**

RESEARCH ESTABLISHMENT LUCAS HEIGHTS NEAR SYDNEY

HEAD

SCIENTIFIC LIBRARY and TECHNICAL INFORMATION SERVICE

An experienced Librarian is required to take charge of the A.A.E.C. Research Establishment Library and Technical Information Service. The Library is the central repository for international atomic energy reports and documentation within Australia, and also maintains an extensive coverage of books and periodicals in all fields relating to atomic energy. It serves some 260 graduates and 350 technical staff,

As the Library covers a broad field of knowledge, attention is being given to developments in technical information services and information retrieval. Commission staff are involved in international work relating to abstracting and information retrieval services.

The Establishment is well served by an IBM360/50H computer and staff experienced in the full utilization of digital computer techniques in various fields. While it would be desirable for the successful applicant to have a knowledge of contemporary techniques in the provision of information services, opportunity will be afforded for additional training in computer automated services.

Applicants should possess a University degree, preferably in Science, together with qualifications equivalent to the successful completion of the Registration Examination of the Library Association of Australia.

Commencing salary will depend upon experience and qualifications and will be within the range of

LIBRARIAN CLASS III \$5,972-\$6,741 (Aust.)

Further information and application forms may be obtained by writing to the Atomic Energy Adviser, Office of the High Commissioner for Australia, Canberra House, 10-16 Maltravers Street, Strand, London, W.C.2. Please quote L.01.

Gallaher Limited

have a vacancy for a

BIOCHEMIST, Ph.D.

who has experience in the field of molecular biology and who is familiar with micro radio autography, nucleic acid preparations, tissue culture techniques, etc. for Research at our Central Laboratories in Northern Ireland.

The position carries a salary which will be negotiated according to age and experience. We operate a first-class contributory pension scheme, and assistance will be given with removal expenses.

Please write, giving full details, to:-

Director of Personnel (BioCh.)

UNIVERSITY OF LIVERPOOL

DEPARTMENT OF ELECTRICAL ENGINEERING AND ELECTRONICS

Applications are invited for the post of Lecturer or Assistant Lecturer in the Department of Electrical Engineering and Electronics. Preference will be given to candidates with research experience in one of the following fields: Electronic Circuit Theory, Solid State Electronics, Surface Studies, High Voltage Engineering, Dielectric Materials.

The salary will be within the scale £1,105 to £2,630 per annum according to qualifications and experience.

Applications, stating age, qualifications

Applications, stating age, qualifications and experience, together with the names of three referees, should be received not later than November 11, 1967, by the Registrar, from whom further particulars may be obtained. Please quote Ref. RV/221/N.

ASSISTANT VETERINARY INVESTIGATION OFFICERS

MINISTRY OF AGRICULTURE, FISHERIES AND FOOD

AND FOOD

At least ten posts for men and women aged at least 23 as Assistant Veterinary Investigation Officers, Grade II. Candidates must be members of the Royal College of Veterinary Surgeons. Post-graduate experience in laboratory research work desirable. The vacancies are at Leeds, Norwich (2 posts), Penrith, Reading, Sutton Bonnington (2 posts), Thirsk, Truro, and Weybridge, STARTING SALARY: £1,326 (at age 23) to £1,779 (at age 32 or over), rising to £2,031. Promotion to Grade I (salary £2,031 to £2,464) in six or seven years (or possibly earlier) for able officers with prospects of further advancement. Non-contributory pension.

Opportunities may arise for short-term service overseas.

overseas.

WRITE to Civil Service Commission, 23 Savile Row, London, W.1, for application form, quoting 266/67. Closing date November 22, 1967.

(1480)

MACAULAY INSTITUTE FOR SOIL RESEARCH

CRAIGIEBUCKLER, ABERDEEN, AB9 201 DIRECTORSHIP

DIRECTORSHIP

The Council of Management of the Macaulay Institute for Soil Research invites applications for the post of Director which becomes vacant when the present Director, Dr. A. B. Stewart, C.B.E., retires on June 30, 1968. The Institute is concerned with the problems of soils and soil-plant relationships and the work is organized in seven major Departments: Soil Survey, Pedology, Spectrochemistry, Biochemistry, Plant Physiology, Microbiology and Soil Fertility, together with a Section on Statistics. For purposes of postgraduate research leading to higher degrees, the Institute is recognized by the University of Aberdeen. Candidates must have high scientific attainment in a field relevant to the work of the Institute. The appointment will be in the grade of Chief Scientific Officer—Lower Band, salary £5,000 per annum, with superannuation under F.S.S.U.

Applications (20 copies), with the names of

F.S.S.U. Applications (20 copies), with the names of three referees, should be sent not later than December 18, 1967, to the Secretary of the Institute, from whom further particulars may be obtained. Overseas, candidates may submit one copy of application. (1488)

UNIVERSITY OF NEWCASTLE UPON TYNE

The University invites applications for the post of LECTURER IN STATISTICS in the Department of Statistics, School of Mathematics. The post is tenable from October 1, 1968, or such other date as may be arranged.

The salary will be at an appropriate point on the scale £1,470 to £2,630 according to age, qualifications and experience. Membership of F.S.S.U. required.

Further particulars may be obtained from the Registrar, The University, Newcastle upon Tyne 2, with whom applications (three copies), together with the names and addresses of three referees, should be lodged not later than November 27, 1967.

(1463)

COCOA RESEARCH INSTITUTE (GHANA ACADEMY OF SCIENCES)

Applications are invited from suitably qualified persons for the following posts in the Cocoa Research Institute, Tafo:

AGRONOMY DIVISION

Senior Research Officer/Research Officer (Statistician) Qualifications

Post-graduate diploma in agricultural statistics with some experience in the design of field experiments on horticultural crops. Tropical experience an advantage though not essential.

(b) Principal Research Officer (Agronomist)

Qualifications*

Post-graduate degree or diploma in agriculture. Training and experience in field experimental studies, preferably with perennial tree crops. Capable of supervising the work of subordinate staff. Good record of published work required.

Ħ CHEMISTRY DIVISION

Research Officer (Soil Chemist)

Qualifications*

Post-graduate degree or qualification in the range of Agricultural Chemist/Plant Biochemist/
Plant and Soil Analyst, with some experience of routine plant and soil analysis.

m ENTOMOLOGY DIVISION

(a) Principal Research Officer (Insecticides Chemist)

Qualifications*

Post-graduate degree in entomology or organic chemistry, with experience in the insecticidal control of crops pests. Good record of published work required and must be capable of supervising subordinate staff.

Senior Research Officer/Research Officer (Entomologists) for Plant Protection

Onalifications*

Post-graduate degree in entomology or organic chemistry, with experience in the insecticidal control of crops pests. Good record of published work required and must be capable of supervising subordinate staff.

Senior Research Officer/Research Officer (Entomologist) for Insect Ecology

Onalifications*

Post-graduate degree in entomology, with experience and a bias towards the dynamics of insect ecology under conditions of insecticide application to field crops. Good record of published work required and must be capable of supervising subordinate staff.

IV

PLANT BREEDING DIVISION

Principal Research Officer (Plant Breeder) to head the Division

Post-graduate degree or equivalent qualification in Plant Breeding. Experience with perennial horticultural crops and good record of published work desirable.

PLANT PATHOLOGY DIVISION

Research Officer (Mycologist)

Post-graduate degree or equivalent qualification in Mycology or Plant Pathology.

PLANT PHYSIOLOGY DIVISION

Principal Research Officer/Senior Research Officer (Plant Physiologist) to head the Division

Qualifications*

Post-graduate degree in Plant Physiology or Plant Biochemistry and interest in environmental effects on plant growth. A reasonable record of published work is necessary.

The Institute, which is entirely residential, is located only 67 miles from Accra and offers attractive living conditions and surroundings.

*Post-Qualification Experience

Principal Research Officer: minimum of 7 years Senior Research Officer; minimum of 5 years Research Officer: minimum of 3 years Salaries (under review) are superannuated.

Principal Research Officer

Ghanaian NC3,800 by NC150 to NC4,400 (£G1,900 by £G75 to £G2,200). Non-Ghanaian NC4,560 by NC180 to NC5,280 (£G2,280 by £G90 to £G2,640).

Senior Research Officer

Ghanalan NC3,500 by NC150 to NC4,100 (£G1,750 by £G75 to £G2,050). Non-Ghanalan NC4,200 by NC180 to NC4,920 (£G2,100 by £G90 to £G2,460).

Research Officer

Ghanaian NC2,100 by NC100 to NC2,600 by NC150 to NC3,350 (Bar) to NC3,500 to NC150 to NC3,800 (£G1,050 by £G50 to £G1,300 by £G75 to £G1,675 (Bar) to £G1,750 by £G75 to £G1,900).

Non-Ghanaian NC2,520 by NC120 to NC3,120 by NC180 to NC4,560 (£G1,260 by £G60 to £G1,560 by £G90 to £G2,280).

Point of entry in the scale depends on qualifications and experience.

Applicants should write for application forms, to be completed and returned not later than November 30, 1967, to the Acting General Secretary, Ghana Academy of Sciences, P.O. Box M.32, Accra.

(A stamped addressed envelope should accompany requests for applications.) Documents

(A stamped addressed envelope should accompany requests for applications.) Documents attached to applications are not returnable.

For overseas candidates application forms are obtainable from the Recruitment Officer, Ghana High Commission, 38 Queensgate, South Kensington, London, S.W.7, or Ghana Embassy, 2460-16th Street, N.W., Washington, D.C., U.S.A., or Ghana High Commission, 75 Albert Street, Ottawa, Canada. (1502)

SCOTTISH PLANT BREEDING STATION

Applications are invited (male or female) for three

SCIENTIFIC OFFICER

posts as follows: (1) a cereal breeder to join the team working on the production of new varieties of feeding barleys and oats; (2) a geneticist to join the cereals team to work on population-genetic problems related to cereal breeding; (3) a geneticist to work in the Potato Department either on the Commonwealth Potato Collection or on economic-genetic problems posed by potato breeding. Applicants for post (1) should have a background in agriculture or agricultural botany; for (2) and (3), a sound training in genetics, preferably with some biometrical experience. Younger applicants will be preferred.

Applications are also invited for an Assistant Experimental/Experimental Officer post, as Junior Field Officer (male applicants only). This Officer will assist in the conduct of field trials of various crops in many different localities in Scotland; he will be based at Pentlandfield but will have to travel widely in due season.

Candidates for S.O. posts should hold a First or Upper Second Class Honours Degree in Science; for A.E.O./E.O. post, a degree or diploma in Agriculture or Agricultural Botany.

Salary for S.O. posts £926 to £1,574 per annum according to experience. Superannuation under F.S.S.U. Salary for A.E.O./E.O. post £744 at age 21 rising to £1,243 per annum (A.E.O.) or £1,365 rising to £1,734 (E.O.) per annum with placing according to age and experience.

Applications giving full personal particulars and naming two referees to Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian, by November 17, 1967.

biochemistry research

Are you capable of doing a wide range of biochemical measurements? Or could you be taught this?

Do you feel bored or restricted in your present job? Have you a B.Sc. or equivalent (H.N.C. considered) in biochemistry, chemistry,

s xxx s

-5

If your answer is "yes" to all these you should consider applying for a job in the Biochemistry Department at Chesterford Park Research Station, where you could join a team of young scientists who are trying to make better pesticides biochemically. This job is not routine, and your advancement would depend solely on your performance. Interested?

Write for further information and application form quoting serial number 139 to:

Personnel Officer (10), Chesterford Park Research Station, Fisons Pest Control Limited, Nr. Saffron Walden, Essex. Telephone: Saffron Walden 3542

DEPARTMENT OF GEOPHYSICS UNIVERSITY OF WESTERN ONTARIO LONDON, CANADA

Applications are invited for the following positions:

(a) Visiting Professor; minimum salary £5,000 er annum; a senior appointment for one year

only;
(b) Assistant Professor; minimum salary £3,200
per annum; minimum qualifications, Ph.D.;
(c) Technical Officer of Professional Assistant;
minimum salary £2,2000 per annum; minimum
qualifications, H.N.C. with experience in electro-

qualifications, H.N.C. with experience in electro-nics but preference given to Honours B.Sc. with experience.

Some Assistantships and Demonstratorships will all be available for graduate students who are accepted for M.Sc. and Ph.D. programmes. For further information, write to Professor A. E. Beck, Head, Department of Geophysics.

(1445)

PORTSMOUTH COLLEGE OF TECHNOLOGY

CHIEF LABORATORY TECHNICIAN

Applications are invited for the above post in the ZOOLOGY section of the department of BIOLOGICAL SCIENCES. Administrative or managerial experience together with knowledge of some zoological techniques is desirable. Salary scale within: £1,020 to £1,220 per annum. Excellent conditions of service.

Application forms are obtainable from: The Staff Officer, Portsmouth College of Technology, Hampshire Terrace, Portsmouth, Hants. Closing date: November 17, 1967. (1448)

GRADUATE CHEMIST WITH AN Honours degree is required for research work on wood preservation. Research Laboratories are in a country district at Frome, Somerset.—Apply Personnel Manager, Cuprinol Limited, Adderwell, Frome, Somerset.

UNIVERSITY OF LONDON KING'S COLLEGE

SCHOOL OF BIOLOGICAL SCIENCES

DEPARTMENT OF BIOPHYSICS

The College requires a Lecturer with research interests in Cell Biology, especially its more molecular aspects. Teaching duties will be within the School of Biological Sciences in undergraduate and postgraduate courses on Molecular and Cell Biology. Salary scale: £1,470 to £2,270, then, subject to review, to £2,630. A London Allowance of £60 plus F.S.S.U. benefits will also be payable. be payable.

Conditions of appointment and application forms may be obtained from the Registrar, King's College London, Strand, W.C.2, and completed forms should reach him by December 31, 1967. (1483) uid reach (1483)

UNIVERSITY OF STRATHCLYDE

DEPARTMENT OF NATURAL PHILOSOPHY

LECTURESHIP

Applications are invited from physicists preferably with theoretical or experimental research interests in lasers or plasma physics for appointment as LECTURBR in the Department of Natural Philosophy.

The successful candidate will be required to take part in undergraduate teaching and to participate in the programme of research in the Department.

Salary scale: £1.470 to £2,630 per annum plus F.S.S.U., with placing according to experience and qualifications.

Application forms and further particulars (quoting \$9/67) can be obtained from the Registrar, University of Strathclyde, George Street, Glasgow, C.I., with whom applications should be lodged by November 30, 1067 (1485)

CORRECTED ADVERTISEMENT

UNIVERSITY OF LEEDS

DEPARTMENT OF CHEMICAL PATHOLOGY

Applications are invited from either medically or scientifically qualified candidates for appointment as Lecturer at a salary on the scale £1,745 to £3,340 (efficiency bar £2,525) for a medically qualified Lecturer or £1,470 to £2,630 (efficiency bar £2,270) for a scientifically qualified Lecturer. Initiat appointment at any point on the scale. Duties involve work in the hospital biochemistry laboratory which the department runs for the General Infirmary at Leeds. The Lecturer will be expected to spend half his time in research, and may work for a higher qualification. The department may be visited by arrangement with Professor G. H. Lathe. Previous applicants need not re-apply.

Applications (three copies), stating age, qualifications and experience, and naming three referees, should reach the Registrar and Secretary, the University, Leeds, 2 (from whom further particulars may be obtained) not later than November 18, 1967.

UNIVERSITY OF GLASGOW

UNIVERSITY OF GLASGUVY
DEPARTMENT OF GENETICS
Applications are invited for the post of Graduate Research Assistant for research project on the chromosomes of self healing skin tumours.
Salary scale: £850 to £1,250 per annum, according to experience.
Applications should be sent to Department of Genetics, University of Glasgow, Glasgow, W.2.
(1497)

Metropolitan Problems

THE first report of the South-East Economic Planning Council is called A Strategy for the South-East (HMSO, 15s.) and the title is the best thing about it. Much of the report is worthy, but most of it is dull. Although there is some stirring talk about the scale on which problems must be tackled, the underlying spirit is one of inaction. For all that the south-east planning council knows, the 1980s will be the same as the 1960s but more so. Faced with the demand to predict the future, the council has summoned up the natural conservatism of the English which makes it possible to embrace the notion of reform without the necessity for actual change. A part of the trouble is that the council seems to have been overawed by the solemnity of its problem. It is true that the south-east of England, which includes London, is the biggest planning problem in England, but the council seems sadly innocent of the plain truth that exactly the same problem has to be tackled by all those required to plan metropolitan areas, from Moscow to Paris. (In the United States, there are at least four such areas to be battled with.) But the council has also been handicapped by its awareness that if it did not say something-even anything-quite soon, there would be a serious danger of being overtaken by events or even of being forgotten altogether.

The nature of the metropolitan problem is now familiar. Metropolitan areas suffer from too many people, too much congestion, problems of pollution and a scarcity of chlorophyll and sunlight. In most places, people—even planners—have only just woken up to the scale of the problem. Less than five years ago, for example, the central problem of the metropolitan area around London may have seemed to be the need to preserve inviolate, or mostly inviolate, the area of administratively imposed greenery which surrounds the city roughly twenty miles from the centre. But then, quite suddenly, people woke up to the fact that the metropolitan region includes 17 million people and 10,000 square miles. Three years ago, this phenomenon was the chief marvel in the South-East Study-one of the then spate of public documents which helped the regional planning councils into being. And now there is at least a suspicion that the scale of the English metropolitan problem has outstripped the geographical terms of reference of the council which has now reported. It may be an accident that much of the natural growth in southern England in the past few years has happened to fall just outside the boundaries of the council's parish—in places such as Swindon, for example—but that is at least one reason for scrutinizing the council's present generalizations with the greatest care.

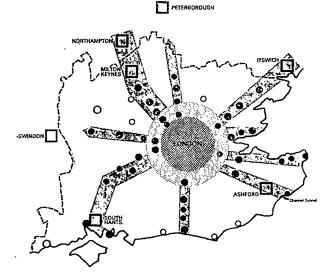

Many readers of the council's proposals will not, however, get that far. Page one of the report is so

littered with begged questions that only the most trusting will penetrate beyond it without a sense of having been cheated. There is, for example, a brief passage about the virtues of London as "a unique international centre for commerce and finance, as a world-wide tourist attraction and as a centre for the arts, education, religion and science" followed by the declaration that the council will try to "enable London to work as efficiently as possible". Those who enjoy the place may be charitable enough to overlook the order in which these virtues have been spelled out, but they will find it hard to see how the council leaps from that to the doctrine that "To this end, the growth of London must be contained. Firm controls must be exercised to relieve traffic congestion, to reduce the difficulties and excessive costs of business firms and to make life as pleasant as possible for the individual Londoner . . . Continual efforts must be made to prevent unnecessary concentration of activities in London, particularly in the central area . . . We fully endorse the concept of holding the resident population of Greater London at or under 8 million . . . " And this, says the council, is why it is essential to develop "city regions around the periphery of the region". This, the council says, is "the only means we see of creating effective counter-magnets that will attract population and industry away from London". It so happens that many of the detailed proposals which the council endorses—the new city on the Solent, for example—are eminently worthy causes on any view of the character of metropolitan planning, but this is plainly an accident and not the consequence of wise design. The council seems to have based its plan on platitude.

How, for example, does the council arrive at the conclusion that the only way to deal with the problems of a metropolitan city is to persuade people to go away by creating "counter-magnets" elsewhere? For one thing, of course, this policy has been tried and found to fail in a host of different ways. For another, there is no earthly reason why people should be denied the pleasures of living in London—if they want themsimply because the council decides that the jobs they do can "reasonably and efficiently be carried out elsewhere". Are the affairs of England to be managed in such a way that the population of London consists almost exclusively of theatre-going politicians and those who assist at the Changing of the Guard? And will it be necessary for those who like sailing at the weekend to train themselves for the kind of jobs which the council has in mind for the Solent city ten or twenty years from now? These exaggerations are absurdities, as even the council would be quick to point out. It is unfortunately less obviously a falsehood to pretend that it is possible to preserve the character of a city whichlike New York or Paris to name only two others—depends for its strength and its creativeness on the unpredictable inventiveness of unsorted people. In other words, the doctrine of counter-magnets is either a dead duck or a death knell.

But what can be done about the traffic jams? These and similar questions provide the plaintive undertone for the council's report. The council's response is to attempt to solve its problems by extrapolating the present into the future, and by embracing the doctrine of counter-magnets to the metropolis. Implicitly the council seems to make the assumption that there will be no change in the character of urban life in the years ahead but only in the scale and extent of it.

This is where technology comes in. With the improvements now in prospect for the decades ahead, there is good reason to re-examine the assumptions on which the doctrine of counter-magnet cities has been based. Specifically, it would be good to know how far it may be possible to give people who live and work in satellite cities a sense that they are nevertheless a part of the metropolis. Why, for example, should not the city now certain to emerge on the Solent be deliberately linked with London by fast train services and cheap telephone circuits in such a way that it would seem no farther away than the outer suburbs of the metropolitan sprawl? The objective should be a physical communications link taking half an hour or so between the two cities—which are only 80 miles apart—and a return fare which is com-

Britain's Small Strong Voice

British politicians are fond of saying that Britain speaks with an authoritative and influential voice at the world's council tables, and there is indeed one set of deliberations in which a British voice, were it loud and clear, would be entirely welcome. In 1969 it is intended that the future shape of an international satellite network should be settled. What is the British line to be? There is a real danger that it will be hammered out on too narrow an anvil between the men from the

parable with but smaller than the price of a theatre ticket. With telecommunications, the prices should and could be such—given the capacity of modern microwave links—that the two cities could cherish the illusion of contiguity. The result could be an exciting extension of the scope of urban living. It would also help to make the south-east of England "work as efficiently as possible".

It is hard to see how the council's strategy will lead in that direction. The principal feature of the council's proposals is a pattern of radial development along ribbons stretching out in several directions around London. The intention is to confine development within the region to these narrow sectors. Even though the council insists that it does not want to see each of these sectors jammed tightly with new developments, the effect of these proposals would be to create a series of linear cities lying along the lines of the new motorways out of London. The trouble, of course, is that the success of a linear city must stand or fall by the efficiency of the transport system which serves as a backbone, and it is entirely ludicrous to expect that the roads now being built will be able to serve the purposes which the council will clearly be expecting of them twenty years or so from now. If, indeed, the council is wedded to the construction of linear cities—and there is a good case to be made for them this is another reason why it should begin by paying some attention to the modern technology of trans-

The council should also do much more than is apparent from its report to translate its problems into the language of what is called systems engineering. To begin with, it should try to create some kinds of criteria which can be used for telling whether one pattern of urban living is more or less efficient than another. As things are, the only criterion on which everybody is agreed is that there should be a vigorous attempt to preserve as much open space as possible around London. It should then set out to define a pattern of urban life-cities, transport and telecommunications—which can give the fullest expression to objectives commonly held to be desirable. In other words, if the committee chose to do so, it could produce a design for the south-east of England that would be worth living in, and could at the same time set a new pattern in regional planning. The glitter of the prizes to be won adds to the disappointment in the council's first report.

General Post Office and the Foreign Office and then trimmed and tempered to suit the demands from the United States. That would be a great opportunity lost.

The manoeuvres in preparation for 1969 have already begun. European interests are talking about the consolidation of their ideas on the outcome they seek from the negotiations, and President Johnson has laid the first American cards on the table. His administration would be willing to see Comsat, the American satellite corporation, relinquish its dominant position as holder of 53.8 per cent of the vote in the international consortium (Intelsat) which runs the network. He would also like to see the Soviet Union and Eastern European countries as partners in the network and, failing that, as co-operating rivals. But he has said nothing about changing the formula that effectively keeps the Soviet Union out of Intelsat—the allocation of voting power on a basis of the amount of traffic sent through the system. (That gives Britain roughly eight per cent of the voting strength, although smaller countries have to share a single vote and the Soviet Union would be down among the one percenters.)

So should the permanent agreement be no more than a hardened version of the present one? There might be nothing so terribly wrong with that. Under Comsat's lead and a strictly commercial philosophy, Intelsat has performed near miracles since the interim agreement was signed in 1964. A good part of the globe is linked by four synchronous satellites. The gap over the Indian Ocean will be filled next year and capacity added all around as the new generation of satellites, labelled Intelsat III, is launched. So far, satellites have begun to pick up transatlantic customers that the cables cannot handle (Spain and Italy have just begun operating receiving stations) and the first over the Pacific was an instant sell-out.

What is wrong with the present international committee is that it leaves too much power in the hands of the somewhat stodgy, traditional communications carriers like the GPO and the American Telephone and Telegraph Company (biggest shareholder and biggest bogy of Comsat). According to the GPO's thinking, satellites are now being cosseted slightly; there is a holding back on extra cables until satellites have had a

Icarus in Parliament

THE asteroid Icarus has made an unexpected impact in the British House of Commons where Mr Keith Stainton, Member of Parliament for Sudbury and Woodbridge, has been asking the Government for assurances that there will be no collision with the Earth next June, when the two objects are predicted to pass within four million miles of each other. Stainton's anxiety is that the predictions of the path of the asteroid may be seriously in error and he has in particular chided the British Government for what seems to him to be an over-trusting reliance on the calculations of the Institute of Theoretical Astronomy in Leningrad. The Government, in the person of Mrs Shirley Williams, Secretary of State at the Department of Education and Science, has replied to Mr Stainton's enquiries with a statement of the Government's confidence that Icarus will indeed miss the Earth.

According to Dr Samuel Herrick, of the University of California at Los Angeles, the uncertainty in the prediction of Icarus next year amounts to about 1,000 miles in the distance of the nearest passage, but this should be reduced to about 150 miles when the ephemeris is corrected to take account of an observation this summer by Dr Elizabeth Roemer at Tucson, Arizona. Dr Herrick has taken a continuing interest in

chance to prove what they can do. But in the last analysis, the Post Office is simply concerned with selling communications at the best possible price. If anybody in Britain is going to give the naive idealistic speech about what satellites can do to break down barriers of geography and politics and to educate the masses, he is not going to come from the GPO. President Johnson has done it in America, but he cannot be expected to suggest that Comsat take a back seat in Intelsat (where it could be outvoted by something less than the combined weight of all the other members).

There are other imbalances to be put right in the permanent agreement. More of the contracts should be placed outside the United States. There should be guarantees that communications networks in other countries should not find themselves, like the neighbour's children, restricted by the Federal Communications Commission's rules for Comsat. There should be some general assembly kind of body to give all of the 59 or so member countries of Intelsat a chance to speak out, even if commercial considerations keep their actual voting power in proportion to their investment in the network.

A lot of guidance could come from Britain on these matters, intricate to the point of tedium. As second in power only to Comsat, Britain is probably the only country which can tactfully suggest Comsat's graceful retreat while asking France and Germany not to launch an independent satellite of their own. The papers in Britain gave considerable space to Professor Fred Friendly's warning from America that lack of planning about satellite communications could create an electronic slum in the sky. The powers that be in British communications have as much and probably more chance than their counterparts in any other country to see that this does not happen.

the motion of Icarus since its discovery by Dr W. Baade at Mount Palomar in 1947. The most recent circular of the International Astronomical Union contains an ephemeris for the asteroid calculated in the United States and collated by Dr Herrick. The asteroid should first become visible in the early days of June next year as an object of the eighteenth magnitude low on the horizon. The closest passage on June 14–15 should be visible from both hemispheres, and the movement of the asteroid towards the Sun should be observable throughout the second half of June. Dr Herrick is planning to circulate more detailed instructions for the observation of the asteroid nearer the time of its closest passage.

The particular interest of the orbit of Icarus next year is that the asteroid will pass close to Mercury as well as to the Earth. This should make it possible to obtain a refined estimate of the ratio of the masses of the two planets. Because of the eccentricity of the orbit of Icarus and the fact that the perihelion lies 0.18 astronomical units from the Sun, precession should amount to about 11 sec of are a century. This implies that study of the orbit may provide a further test of predictions of general relativity, if not on this passage then on some future occasion.

Two Cheers for Nuclear Physics

CRITICISM of the way in which the UK has supported big science was given by Sir Harry Melville, the retired chairman of the Council for Scientific Policy, in the Appleton Memorial Lecture to the Institution of Electrical Engineers. In nuclear physics, Sir Harry said, the home effort was certainly too large if the powerful international facilities to which the UK contributes were taken into account. "By arranging better collaboration in Europe, considerable economy could have been achieved in the construction and operation of machines of moderate size." It was argued, Sir Harry said, that nuclear physicists needed to be trained on medium-sized machines if they were to use the "Yet many countries bigger international machines. in Europe do not have national machines and they still work effectively with the international facility.' national prestige were to be an index of success, the accelerators in the UK had been badly timed.

Big projects well timed, on the other hand, could give the country a lead for many years over other countries and add to its scientific prestige. telescopes, Sir Harry thought, had been well timed and, although the capital cost of the equipment was high, the costs of running telescopes were relatively low. Radio astronomers were also more useful in industry than others, because of their varied experience. But Sir Harry had nothing kind to say about big optical "In optical astronomy the telescopes in Britain. utilization of telescopes is very low indeed because of the atmospheric conditions and it is questionable whether any large telescope should ever have been installed in this country. The natural trend is to erect telescopes in countries overseas where observing conditions can be relied on for long periods of the year."

The next few years would be of great importance to the universities. The Government had announced the financial provision for the next five years, and the research councils knew how much they would be getting in the next three years. Sir Harry was unimpressed. "The increase in moneys year by year is extremely modest, having regard to the job which has to be done, especially in science. A good deal of re-thinking and pruning will have to be done if quality is to be maintained . . . there can be a very real danger of stagnation if vigilance is not maintained and management is not made effective."

ELDO Hopeful

WITHIN the next fortnight, all being well, the next launching in the ELDO programme will take place from Woomera, Australia. ELDO staff are hoping that the launching, called F6/2, will make up for the disappointment of the last launching, which went perfectly until after the separation of the first and second stages. The second stage engines failed to ignite. ELDO is confident, however, that the failure did not reflect on the design of the second stage, but was caused by an electronic failure. For the next firing, simple modifications have been introduced to prevent the same thing happening again.

For the F6/2 launching, the second stage will again be live, and the upper stages will carry the basic elements of systems intended for full test in later flights.

It will be the first flight for testing all the separation systems for all three stages and for satellite injection. After separation, the second and third stage plus satellite will continue in ballistic flight a small distance from each other. The impact zone, in the Pacific some 2,300 miles from Woomera, will be reached in about 18 minutes.

Robbing Peter, Paying Paul

from our Oxford Correspondent

OXFORD colleges vary greatly in wealth, from the older men's colleges—St John's, Christ Church and All Souls—with their munificent endowments, to the penury of the newer men's colleges and most of the women's. Shortage of money has put the members of poorer colleges at a disadvantage in many ways; it is difficult for them to appoint tutors in recondite subjects, so that many students have to be taught outside their colleges. Stipends at some women's colleges have been very considerably lower than those at men's colleges, and there have been far fewer tutors for the same number of undergraduates.

Congregation has now, however, passed a statute which, it is hoped, will eliminate these disparities. Colleges are to contribute to a university fund on a sliding scale so that the poorer colleges will be paying nothing and the richer ones up to a quarter of their income above £150,000. The fund will then be distributed among the poorer colleges so that eventually the endowments of all colleges will exceed £600,000, £200,000 more than the figure recommended by the Franks Commission. The contribution of colleges to the fund will be assessed according to capital rather than income. The Franks Commission had originally recommended an assessment on the basis of capital as being ideal, for certain colleges have large amounts of capital yielding low interest rates, but the commission concluded that this method of assessment would be too difficult to undertake, and decided that contributions should be evaluated on the basis of college incomes. The problem of valuation now lies with the University Chest and the College Contributions Committee, which will be administering the scheme from July 31 next year.

Transitional arrangements have been made: the two graduate colleges, St Anthony's and Nuffield, which specialize in the social sciences, will be taxed by the university at a lower rate than undergraduate colleges. For some time, grants to poorer colleges have been made by the Common University Fund, but the last payments of this kind have been made in the form of £80,000 to be divided between three colleges, and all the work of making the colleges financially equal will now be carried out by the Contributions Committee.

Hydrofoils or Hovercraft?

THE British interest in hovercraft has tended to overshadow hydrofoils, another interesting development. Mr R. Gresham Cook, Conservative MP for Twickenham, is alarmed about this, and opened an adjournment debate on the subject in the House of Commons last week. While Britain has been building 40 hovercraft, he said, nearly 1,000 hydrofoils—craft the bows of which are raised from the water by the action of wing-

like foils—were in operation all over the world. Even in rough water, the ride in a hydrofoil is comparatively smooth-better, it seems, than in a craft of the same weight without hydrofoils. Mr Cook said that hydrofoils are cheaper to manufacture than hovercraft, although more expensive than conventional passenger

In April this year, the Ministry of Technology established a working party to examine the design, construction and operation of hydrofoils. Its chairman is Mr A. Silverleaf, deputy director of the National Physical Laboratory, and among its members are Mr Peter Dory, who operates a hydrofoil service between Jersey and Guernsey and the French coast, and Mr M. N. Parker, of the British Ship Research Association. So far the committee has been involved with a survey of the possible markets for hydrofoils; when this is finished it will turn to the research side.

Research on hydrofoils has in fact been undertaken at the Ship Division of the National Physical Labora-This has been work of a fairly fundamental nature, including studies of the lift produced by the hydrofoils and the forces experienced by them. There has also been some work on propeller design and on the behaviour of the hydrofoils in waves. Experience at the NPL confirms that hydrofoils ought to be able to manage in conditions at sea. Costs depend greatly on the degree of sophistication. At the NPL, work has been carried out on surface piercing foils, which are likely to need less sophisticated control than other types. With surface piercing foils, changes of speed are automatically taken care of by the shape of the foils. If, for example, the craft slows down and sinks into the water, a greater area of foil becomes an effective lift surface, and the necessary lift is maintained. If speed is increased the effective area of foil is reduced, and the craft retains roughly the same attitude. Fully submerged foils, on the other hand, call for more complicated control systems, more like those of aircraft.

Many of those involved deny that there is any conflict between hovercraft and hydrofoils, and say that there is room for both. In a recent paper presented to a Canadian symposium (and reprinted in Flight International on October 19) Mr Christopher Cockerell, inventor of the hovercraft, suggested that hydrofoils would be more suitable at speeds below 40 knots and sizes of less than 100 tons. Mr Cockerell's paper suggests that hovercraft and hydrofoils would be similar in cost, but hovercraft pay a heavy penalty by the lack of suitable engines. With better engines, fuel costs, which amount to 25 per cent of total operating costs, could be reduced by a factor of two or three.

Regulated Surpluses

NATIONALIZED industries in Britain may from time to time complain that they are starved of capital, but there is no doubt that they are generously supplied with decrees by the Government about the conduct of their affairs. The most recent of these is the White Paper on the economic and financial objectives laid down for the various industries (HMSO, 1s. 9d.). For practical purposes, this document is a revised version of that which appeared in 1961 and which first laid it down that nationalized industries should earn a surplus on the capital employed in their businesses which would be comparable in many ways with the profits earned by commercial industries. issue is important because of its influence on the prices charged by the several industries and because of the way in which it affects decisions about large items of capital expenditure.

The new document is more a statement of general principles than a set of detailed instructions—the ministers responsible for individual industries will issue them. The Treasury, which determines general policy, suggests that a revision or at least a restatement of policy has been made necessary by the "important technological changes and discoveries of natural resources" since 1961, but it is also clear that the anomalous differences which have sprung up between different industries have contributed to the need for rationalization. No doubt the Government has in mind the way in which the electricity industry, now wishing to invest in nuclear power stations, should aim at a higher rate of return than the gas industry, now unexpectedly prosperous.

Differences like these should be comfortably ironed out by the doctrine, now promulgated, that decisions about alternative forms of capital investment should be based on the same kind of calculation—one which has the effect of making the effective rate of interest a cool 8 per cent. This is the rate the Central Electricity Generating Board will have to use in calculating the economic balance between nuclear reactors and conventional power stations. This, too, is how the Gas Council will have to make decisions about alternative ways of using gas from the North Sea. This is a good start, and it is also sensible that the new statement of policy should emphasize the importance of linking the prices charged for the products and services of the nationalized industries with the marginal costs of providing them. If this means that the new commercial Post Office will charge less for trunk telephone calls, everybody will be delighted. But it is also important that the new policy statement emphasizes that industries need not slavishly aim to earn the surpluses laid down for them, for this may help in future to avoid some of the absurdities about electricity prices which there have been this summer. In other words, the new White Paper is full of good sense, although it does not go so far as to suggest that ministers should in future refrain from nullifying the benefits of sound policy by pointless interference.

More Money for France

A SUBSTANTIAL increase of the spending of the French Government on scientific research and development is allowed for in the budget for 1968, now adopted. There will be an increase of 17 per cent in the total cost of supporting what is described as scientific and technical research through the public purse, so that the amount spent in the year ahead will be approximately 1,591 million francs. The programme for assisting the development of computers, and the programme of space research, will each receive an extra 20 per cent. One of the greatest of the various increases in the year ahead is that for the support of space research, which will be absorbing an extra 68 million francs. Support for science and technology through the educational budget is substantial, and will take an extra 96 million francs in 1968.

Insuring Nuclear Power

VERY soon, the Paris convention on third party liability in nuclear energy will come into force. The convention, which provides the principles on which international agreements on nuclear liability are based, was signed in Paris on July 20, 1960, but does not come into force until it and ar additional protocol are ratified by five governments. The convention has now been ratified by Turkey, Spain, the United Kingdom, France and Belgium; the additional protocol, which is designed to avoid conflict with another international conventionthe convention on civil liability for nuclear damage, defined by a conference in 1963 convened by the International Atomic Energy Agency—has been signed by the same group, with the exception of Turkey. Turkey is now on the verge of ratifying the protocol, whereupon the whole convention will come into force.

The subject is complicated. Briefly, the convention provides five principles on which legislation should be based. The operator of the nuclear station is absolutely and exclusively liable—without proof that it is his fault —for any accident, but only if claims are made within ten years of the incident. The convention limits the amount of liability, in principle, to \$15 million, and obliges the operator to cover his liability by insurance or otherwise. All claims arising from the same incident should be dealt with in the same court, in the place where the incident took place, and all countries who are party to the convention are obliged to accept the court's rulings. In 1963, the provisions of the convention were extended to provide additional compensation, up to a value of \$120 million, through State intervention.

The convention falls under the jurisdiction of the European Nuclear Energy Agency, which has now published a review of the legislation which obtains in fourteen OECD countries and of how this meets the needs of the Paris convention. Most of the countries have legislation which incorporates the principles of the convention, and some go beyond it. There are, however, some differences—in Japan, for example, accidents during transport are the liability of the consignee. In Germany, there is no provision to limit liability in the event of force majeure. Most countries incorporate clauses which free the operator from liability in such cases, or when the claimant was injured as a result of his own negligence or a wilful act. In the United Kingdom, when the victim has been guilty of committing an act with the intention of causing harm or with reckless disregard for the consequences, the amount of compensation may be reduced. In the United States, the cost of an accident can be even greater—the law provides for liability of up to \$560 million.

Books to Borrow

"NEITHER a borrower nor a lender be" may have been good advice for Hamlet, but luckily for the British general public there are people who do not take it too seriously. The National Central Library borrows and lends more each year from its stock of volumes, which has doubled over the past five years to the present total of 364,000. 1,037 current periodicals are taken, 68 of them being in Slavonic languages. The library, which is largely financed by the Department of Educa-

tion and Science—£141,000 last year—has just produced its annual report for 1966-67.

The British library system works on a two-tier basis, with the central library available to answer requests from both parts. Most libraries belong to regional systems, which are as far as possible selfsufficient. Unsatisfied queries are passed on to the central library. Other libraries which, for one reason or another, are not included in any regional system form the second tier and have direct contact with the central library. As overall centre of the national interloan system, the central library handled 136,660 requests during 1966-67, with 77.5 per cent success, compared with 128,567, 75.2 per cent, in the previous year. Through the co-operating libraries the central library has access to some 20 million volumes. 7,969 overseas requests were received, of which 83·1 per cent were satisfied, as were 72 per cent of the 9,954 requests made by the central library to those abroad. The total number of applications received by the library rose by 6.3 per cent and were handled despite staff shortages. A successful year was recorded by the library, but it ended with the resignation of its chairman because of ill health. Lord Elgin, associated with the library since its reconstruction in 1930 and chairman of the trustees since 1955, had presided over many important developments in the library's affairs.

Another library publication appeared this week, a list of the current serials received by the National Lending Library for Science and Technology at Boston Spa, Yorkshire. (HMSO, £2.) The alphabetical list has been produced as a by-product of the recording system at the library, and, it is stated, may not include a certain number of titles which are in fact available. Only those titles which were current and at the library in March 1967 are included, but not those which were on order. The list is not intended to deter those who would like to borrow periodicals that are not mentioned, as the library relies on such requests for titles of serials that should be obtained. A large number of cyrillic titles are included in the total of 26,000, and for the first time the social sciences are covered.

Fission of Physics Journals

THE Institute of Physics and the Physical Society (which is the name for a single learned society) is embarking on an important change in its publications policy. The Proceedings of the Physical Society is to be split into three sections to be known as Journal of Physics A, B and C dealing respectively with general physics, atomic and molecular physics and solid state physics. The intention is that contributions to the three sections will appear six times a year in alternate months. The price of subscriptions to the new journals is to be £40 (for 18 issues a year) which is more than a proportionate increase on the cost of £24 for one subscription to 12 issues of the *Proceedings*. It will, however, be possible for non-members of the society to take out separate subscriptions to the three parts at a cost of £15 each.

By making this change, the British society is clearly following in the steps of the American Physical Society, which publishes *The Physical Review* and which split this into separate sections at the beginning of 1967. Only time will tell whether the obvious advantages of

these changes will outweigh the disadvantages. No doubt readers will appreciate the preselection of articles which separate publication makes possible. To set against this may be a slight increase of the time-lag before publication and the possibility that important articles will not reach as wide a readership as they deserve. Although it is known that the British society would like to see a wider integration of scientific journals on a European basis, the splitting of the journals is not directly related to developments of that kind.

The society has also in the past few weeks lost through retirement Dr A. C. Stickland, editor and deputy secretary. Dr Stickland joined the staff of the Physical Society twenty years ago. She has been appointed managing editor of the *Annals of the International Years of the Quiet Sun* under the auspices of the International Council of Scientific Unions.

Making the Most of Manpower

A POLICY conference on highly qualified manpower held in September 1966 is agreed to have raised more problems than it solved, but the report just published by the Organization for Economic Co-operation and Development (OECD), which ran the conference, includes an impressive list of recommendations.

Means of adapting educational systems to meet economic needs were discussed, together with the use of manpower by employers. In an age when science and technology are expanding quickly, education and training are vital and must be continued throughout the working life of each individual if accumulated knowledge is not to become obsolete—this is a familiar theme of OECD. The report lists five areas in which research must be done if the problems involved are to be pinned down. These cover improvement and standardization of statistics of personnel and the reasons why different people chose various academic subjects, training and jobs. Only by following individuals through various stages in their careers will the important influences be discovered.

The conference recommends to the member countries that they should develop systematic policies for the training and efficient employment of highly qualified manpower to meet their economic needs. The aim should be to provide education at school, university and

in the job which adds up to a coherent whole for each individual, as well as providing a complete information service on employment situations and possibilities so that the best use is made of qualified workers. National bodies would have to be set up to organize the required research and put results into effect. On an international level, OECD members were asked to continue the present work by referring back to the governments concerned. A further conference is proposed.

Foot and Mouth Disease

More than 21,000 animals have so far been slaughtered during the fastest moving epidemic of foot and mouth disease for nine years in Britain. The number slaughtered includes 7,614 cattle, 6,709 sheep and 7,335 pigs. There have been 87 separate outbreaks.

The causative agent is a spherical RNA virus, 22 millimicrons in diameter and designated sub-type O1. Of the seven immunological types so far characterized, foot and mouth disease in Britain is usually attributable to the three types O, A and C. There is no reason to believe that type O1 is particularly virulent, and it has indeed occurred in several European countries during the past few years. The most recent alarming outbreak of the disease in Northumberland and Southampton in 1966 was also caused by type O1.

The present outbreak was confirmed on October 25 at a farm near Oswestry in Shropshire, at a time when a large animal market was being held in the vicinity. There seems, however, to be no link between these cases and outbreaks in other counties. The veterinary service of the Ministry of Agriculture fears that there may well be an undisclosed source of infection in the area. It is possible, but unproved, that this epidemic is the result of infected meat imported from abroad. The virus can survive for days outside the animal body. It can be transmitted mechanically by direct contact from one animal to another, on cars or on the beaks and feathers of birds; transmission can also be airborne. As long as trade continues with infected countries, sporadic outbreaks in Britain will occur.

Another feature of the virus is its tendency to undergo antigenic variation. A vaccine incorporating the three types O, A and C is already being used on cattle in France, Belgium and Holland with encouraging results. The cost of such a vaccination scheme in Britain is said to be prohibitive—far greater than the cost of slaughter—and would, in any case, be impracticable. This is why there is a tendency to believe that charity begins abroad. Vaccine produced at the Animal Virus Research Institute, Pirbright, is exported to Turkey, Bulgaria and Greece. The institute also serves as the world reference laboratory for typing foot and mouth virus and for collecting information about epidemics.

How to Deal with Oil

"The greatest peace-time operation ever mounted in the United Kingdom." This is how the recent report compiled by L. R. Beynon, British Petroleum Company, describes the efforts to fight the oil pollution after the Torrey Canyon incident. Far from being a mere account of events, the report includes the action which was taken and its effectiveness, and possible alternatives and considerations for future treatment of similar disasters.

The beginning of the operation was actually a series of failures. The rough weather did not make salvaging operations easy and pollution on this scale had never occurred before. The floating boom which had been intended to encircle the ship and reduce the spread of oil had not arrived. Furthermore, it was not until ten days after the ship had run aground that the air attacks were begun to fire some of the oil slicks and to destroy the remaining cargo. In all, 160,000 lb. of high explosives, 10,000 gallons of aviation kerosene, 3,000 gallons of napalm and several rockets were used to burn the oil in the ship and the surrounding area of sea.

Early attempts on the Cornish coast to fight the oil slicks which were building up on over a hundred miles of beaches are described as largely uncoordinated and haphazard. "Detergent was being sprayed or slopped from small boats with little effect and its application to polluted beaches and rocks was, in general, remarkably inefficient and wasteful." Detergent treatment without subsequent water washing added to the distressing situation instead of abating it, and booms which had been installed at Porthleven Harbour proved useless. It was not until troops had been drafted into the area and vast supplies of detergent were introduced that any encouraging results were seen.

One possible method for fighting oil pollution on the sea involves the use of vessels designed to skim the oil from the surface. Such vessels have been used in sheltered harbours but cannot be considered as sea going vessels. The report suggests that the problems of skimming oil off the sea might be reduced by the application of coagulants and floating absorbents; but the problem still remains of collecting the coagulated contaminant in open sea conditions. Another alternative is to sink the oil using granulated materials of high density. The sunken oil, however, could damage marine life and there is a danger that it would not be rendered permanently immobile and could repollute the water. The destruction of oil by burning on a damaged tanker is impracticable, the report says, and attempts to burn oil floating on the sea are inefficient. The only practical means of dispersing the oil is by the application of detergent: in all, about one million gallons were used to emulsify oil at sea in the case of the Torrey Canyon.

Several lessons were learned about operations on and close to shore. Booms were found to be effective in preventing the passage of oil only if exposed to sea conditions with currents of under two knots or waves less than a foot high. Where oil reaches appreciable thickness in harbours, sewage vehicles can be used to skim off the oil, or absorbent substances such as straw, ash and plastic materials can be used to absorb the oil. Oil stained harbours and estuary walls can be cleaned effectively by spraying with detergent and then hosing down with jets of water. The quickest method of cleaning a sandy beach involves the use of an agricultural rotary cultivator. This breaks up the oil and mixes it with sand, and detergent is then sprayed on.

For the future, the report recommends the building of tankers with high speed pumps to transfer the oil from a damaged tanker, some efficient means of mixing the sea water, oil and detergent after spraying the oil slicks and the development of cheaper, less toxic but effective detergents.

Step Nearer to Space Stations

from a Correspondent

Ir is curiously appropriate that one of the space "spectaculars" marking the fiftieth anniversary of the Russian Revolution should have been a demonstration that a technique fundamental to building orbiting space stations has been mastered—that is, the automatic rendezvous and docking of two spacecraft. It is to that astonishingly practical analyst of the laws of space exploration, Tsiolkovsky-whose principal work was done in isolation and hardship in the later days of the Tsars—that is due the main credit for the space station concept—a combination of springboard to the stars and the most economic means of obtaining an extra-terrestrial observing platform. After the revolution, Tsiolkovsky received the recognition and applause he no longer sought, but his message is remembered. As the Russian space strategy emerges, it sometimes seems that Tsiolkovsky's ideas are the conceptual blueprint for it.

It may be months or longer before a space station exists in orbit, but this is probably now the Russian intention. Such a contraption could be of great value in its own right, both as a manned observatory for a wide range of surveys and for astronomy freed from the encumbrance of atmospheric instability. Several senior Russian scientists—at the Belgrade Astronautical Congress and elsewhere—have recently expressed unqualified enthusiasm for the observational possibilities. Equally, a space station could be used as a staging post for assembling the components of the substantial "spaceship" required for the manned leap to the Moon. The basic techniques are the same, and the smooth encounter, joining and separation of Cosmos 186 and 188 show these no longer pose insuperable problems. Similar manoeuvres will have to become routine and a considerably higher orbit achieved before a multi-component space station can be assembled.

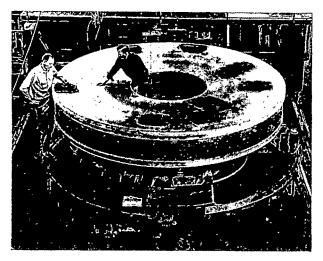

But the Russian claim that the automatic link-up is the key technological advance in the present phase of space development seems justified.

In last week's encounter, Cosmos 186 was the "active" partner, and was subsequently recovered. Independent evidence indicates that Cosmos 186 and 188 were of Soyuz dimensions (3×9 m) and can therefore carry a man, or even men. The active Cosmos 186 seen on television pictures was equipped with brief curved "wings", which suggests a certain degree of built-in aerodynamic control. Hints of such a development for the more complex manoeuvres of the future emerged in the remarks of an influential Soviet engineer at one of the technical sessions of the Belgrade meeting. It would obviously be more convenient if a returning cosmonaut could arrange to touch down near home rather than abroad, even if in future he will also be equipped to land in the sea.

Quartz Mirror for Kitt Peak

The fusion of fifteen tons of quartz into a mirror blank takes the astronomical telescope at Kitt Peak National Observatory, Arizona, one step nearer completion, but there is still more than two years of optical work to be done on the mirror before it is ready for use. The General Electric Company of the USA made several attempts at fusion before successful treatment of the 158 inch mirror blank at 3,300° F in a specially

designed furnace. The mirror will now be transported from the works in Ohio to Kitt Peak where the grinding and figuring of the surface to an accuracy of one millionth of an inch will be carried out.

The world's largest quartz mirror blank, now ready for shaping and polishing for the Kitt Peak telescope.

When completed, the Kitt Peak telescope will be the largest telescope to use a quartz mirror instead of conventional glass. Quartz has the advantage that its expansion with temperature is one fifth that of ordinary glass, as well as being very hard and rigid. According to Mr R. A. Popp of GE(USA) it can be polished and finished faster than borosilicate glass. The Kitt Peak installation will be the first big telescope to use the Ritchey-Chrétien optical system. This form is not new, but is only now being generally adopted for astronomical telescopes. The Newtonian-Cassegraine system, used for almost all existing large telescopes, gives perfect axial imagery, but its inherent coma limits the useful field size, particularly at the prime focus. The Ritchey-Chrétien form gives a much larger coma-free secondary focus but the prime focus image has quite heavy spherical aberration. In either form the field of the prime focus can be extended by the use of afocal lens systems, but rather unexpectedly these give considerably useful fields on the Ritchey-Chrétien telescope.

The Optical Design Group at Imperial College under Dr C. G. Wynne has investigated field corrector systems for such telescopes as the 200 inch at Mount Palomar (Newtonian-Cassegraine), Macdonald (Ritchey-Chrétien) and Kitt Peak. The 108 inch Macdonald telescope, like that at Kitt Peak, is to use a quartz mirror and is at present under construction.

Research into Blindness

Wanted—one million pounds by the "Fight for Sight" campaign to provide an annual income of at least £50,000 for work undertaken at the Institute of Ophthalmology in London. Government financial aid to the institute is insufficient to cover the cost of the work; consequently, the institute must augment its income by private benefaction. The president and emeritus director of research, Sir Stewart Duke-Elder, was also the prime mover in establishing the institute in 1946, in association with Moorfields Medical School

and as part of the University of London. All the teaching and part of the research costs are met by grants from the University of London and the institute has so far received £419,345 from other sources. This has enabled the setting up of two research fellowships for the study of glaucoma and a fellowship has also been initiated for the study of eye diseases and related problems, particularly in children.

The research work in progress is extremely varied, but with more than five million blind children alive in the world today there can never be too many investigations into the causes and cures of blindness. Some types of blindness are caused by hereditary factors-retinitis pigmentosa or degeneration of the retina, for example. Work in this direction is conducted at the molecular level. Other types of retinal abnormalities are caused by environmental factors, as seen in premature babies who become blind when supplied with oxygen shortly after birth. Increased blood pressure or hypertension is another important factor determining defective sight. Under the direction of Professor N. Ashton, this condition is being induced experimentally in animals with a view to determining the cause of the defect. The use of lasers for bloodless surgery on the anterior part of the eye (iridectomy) is also being investigated at the institute and a laser slit lamp—really an ophthalmoscope incorporating a laser has been developed there. Other projects include an investigation of visual pigments, laboratory diagnosis of eye diseases, electron microscopy and serial reconstruction of the retina as well as efforts to improve underwater vision.

The research teams are, however, hindered by lack of space. The construction of another floor at the institute is being debated but, until something definite is arranged, the number of staff will be limited and research programmes will take longer to complete.

Generator for Surrey

THE rewards of collaboration between universities and industry would appear to outweigh any possible loss of academic freedom. This is true, at least, for the University of Surrey. The Standard Telecommunication Laboratory has just presented the Electrical Engineering Department with a 2 million volt Van de Graaf generator. The generator is not new; it is, in fact, eleven years old and STL had no further use for it, but it seems admirably suited to the intentions of the department.

Professor D. R. Chick, of the Electrical Engineering Department, has a research team working in collaboration with the UKAEA on the implantation of heavy positively charged ions into semiconductors and metals. The generator will be used to implant impurities directly into silicon and germanium. It will also be used for X-ray and neutron studies of interest to the physics department and the radiation unit of the university. The machine will also be an invaluable teaching tool in the department's new M.Sc course on nuclear radiation and semiconductors which is to be run in collaboration with other departments of the university and the UKAEA, and which starts in October 1968.

This M.Sc course will have its emphasis on the experimental and engineering techniques of radiation production and detection, and of diagnostic methods

of investigating the behaviour of semiconductor materials. The student will also gain a sound background in nuclear and atomic physics and solid state theory. The object of the course is to produce nuclear and solid state technologists able to apply themselves to problems which do not fall into the individual category of nuclear physics, solid state physics or electrical materials.

Money for Caltech

A CAMPAIGN to raise \$85.4 million in capital funds has been launched by the California Institute of Technology. This includes \$20 million for the endowment of faculty salaries, \$30 million for new buildings and renovations and \$35 million for the increased operating costs of its academic programmes and physical plant. The president, Dr L. A. Dubridge, suggests that the most urgently required buildings are a geophysics and planetary sciences laboratory (\$2.45 million), a cyclotron building to house a particle accelerator (\$1.7 million), an applied mathematics building (\$1.625 million) and an engineering laboratory to provide room for an increasing variety of projects in the fields of electronics, materials, aeronautics and hydraulics. Four halls of residence are also required for unmarried students (\$2.425 million) and a new physical education building is also needed (\$1.15 million). Last but not least, a building is needed to house the Buildings Operations department, already the largest business activity in the city of Pasadena (\$2.425 million).

Caltech already owns the land necessary for the new buildings, according to Dr Dubridge, and some of the buildings will be located on the main campus.

Scant Recognition

The discovery of radium by Pierre and Marie Curie is being marked by an exhibit in the Atomic Physics Gallery of the Science Museum, London. Visitors should go up to the second floor and proceed to section 44 where, if they look carefully, they will see an unobtrusive picture of Marie Curie bearing the following inscription: "Becquerel discovered the radioactivity of uranium in 1896 and in 1898 Madame Curie showed that thorium was also radioactive. In the same year, Pierre and Madame Curie, working together, succeeded in separating from uranium ores two much more strongly radioactive elements which they named polonium and radium. In her later life, Madame Curie played a greater part in the application of radium and other radioactive substances in medicine."

It is to be hoped that the museum will do better when, next month, it celebrates the 25th anniversary of the first controlled nuclear pile, built by Enrico Fermi at Chicago.

'Nature' Appointment

DR JOHN TOOZE, a lecturer in the Department of Biophysics at King's College, London, will join the staff of Nature as Assistant Editor early in the New Year. Dr Tooze was educated at Jesus College, Cambridge, and has spent some time at the biology laboratories at Harvard University on a Wellcome Trust post-doctoral fellowship. In the next few months he will be helping with the production of the journal.

Parliament in Britain

Education

THE Government should keep an open mind on the question of loans and grants for postgraduate education, according to Sir Edward Boyle, Opposition spokesman on education. He was speaking in a debate on the Queen's Address, in which Conservative members took the opportunity of criticizing Mr Patrick Gordon Walker's handling of comprehensive schooling and the British Museum. Nothing should be done to deter working class children from going to university, he said, but if we wanted a large expansion in postgraduate education in the seventies, the possibility of a loan element should not be forgotten. Sir Edward also said that the Government's new target figure of 220,000 to 225,000 students by 1971 was too low, although it was well above the Robbins predictions. The vice-chancellors' committee, he said, had put the figure at 245,000. Why had the Government not accepted this?

Mr Gordon Walker first explained his position on the British Museum. He had been charged, he said, with reversing a firm decision to go ahead with the Bloomsbury scheme. This was simply not true. "There was no clear decision by the previous government, nor any firmness of action or clarity of purpose. On the contrary, it was a sorry tale of indecision." Several members were reluctant to accept this version of events, but Mrs Lena Jeger leapt to the defence of Mr Gordon Walker. It was, she said, an unbearable hypocrisy for Conservative members to appear as the sudden friends of the British Museum and sudden lovers of books. The recent report of the British Museum Trustees was an indictment of successive governments. It was certainly no comfort to any of them.

Finally, Mrs Shirley Williams was able to answer Sir Edward's question. The vice-chancellors' estimate of 245,000 students by 1971 was simply the adding together of the reasonable ambitions of all vice-chancellors, and was not put forward as a collective view. The target of 225,000 would be met without damaging other parts of higher education by trying to shift resources even further towards university expansion. (Debate, November 3.)

Child Care

LORD STONHAM, Minister of State, Home Office, said that the Home Secretary had decided to establish a development group within the Children's Department The group would work in close and Inspectorate. co-operation with the universities, the professional associations and organizations such as the National Bureau for Co-operation in Child Care, seeking to supplement and support the research and development work which these bodies already undertook. The Home Secretary had also proposed to the local authority associations that the present Advisory Council on Child Care and the Central Training Council should be reconstituted and amalgamated to become the central forum for the co-operative discussions and steering of research, development and training in child care. The reconstituted council would be supported in its work by the new development group and by the Home Office Research Unit, both of which would undertake projects within programmes drawn up by the council and approved by the Home Secretary and the local authority associations. (Debate, October 25.)

NEWS AND VIEWS

Why Physics is Fun

Physics at its best is nothing if not elegant. memorable experiments are somehow distinguished by their simplicity and even by their cheekiness. With the benefit of hindsight, for example, it is plain that Rutherford and his associates in the 1900s were asking altogether too much of the simple apparatus with which they sought to understand the processes of radio-This means that their success seems even more remarkable. But the same is also true of the way in which J. J. Thomson first measured the ratio of charge and mass for an electron and—for that matter of the way in which Joule established the quantitative relationships between different kinds of energy. Simple apparatus and clever design can do more than merely establish a proposition: by their simplicity they carry extra conviction. And to make the process even more absorbing, the very best of the experiments in physics contain an element of paradox. Something that might be expected to happen fails to happen.

But is there not a danger that these qualities will be lost by the coming of the new style of working in physics? This is a reasonable question to ask. It is, however, pleasing that the way in which it is now necessary for large groups of people to work closely together on the design and the conduct of a single experiment has not meant a sacrifice of elegance but, if anything, the opposite. A great many of the experiments carried out in connexion with the large particle accelerators, for example, have benefited from the close and detailed study of a group of men under pressure to make the best possible use of expensive equipment and restricted access to it. The result is that experiments like those on neutrinos and muons designed at CERN and Brookhaven in the past few years are in the best traditions of elegance in physics. It is true, of course, that string and sealing wax have no place in circumstances like these, but these were never essential ingredients of Rutherford's experiments either. What matters is the directness of the design.

But elegant experiments are to be found elsewhere than in attendance on the big machines. An intriguing illustration of this has now appeared in *Physical*

Gould's Belt Defined

EARLIER calculations of the relationship between the local cluster of stars and the rest of the galaxy have been confirmed and refined by an article by Dr F. V. M. Clube of the Royal Greenwich Observatory (Mon. Not. Roy. Astron. Soc., 137, 189; 1967). Dr Clube has made use of several recent measurements of the velocity and position of the stars in the local cluster as well as information about the distribution of neutral hydrogen in the nearby parts of the galaxy obtained by radio astronomers in recent years. His general con-

Review Letters (19, 1049; 1967). Drs F. C. Witteborn and W. M. Fairbank there describe an experiment to measure the free fall of electrons in a vacuum enclosed by a copper tube. The immediate object is to test the predictions of Professor L. I. Schiff and M. V. Barnhill a year ago that in circumstances like these the gravitational force on an electron is exactly cancelled out by electrical forces. These, in turn, are supposed to arise because of the way in which the balance between positive and negative electrical charges within the metal is distorted by the presence of a gravitational field. In the experiment which Drs Witteborn and Fairbank have designed, electrons from the cathode are tracked upwards through a metre long copper tube by a moderate electric field. To make sure that they travel along the axis of the tube, the whole apparatus is placed within a superconducting solenoid which provides a magnetic field of 7,000 Gauss or more. The technique is to measure the time taken by the slowest electrons to travel the length of the drift tube and to calculate from this the upper limit to the effect of gravitational force on these same electrons. The first result of this experiment is that the effective force is less than nine per cent of that appropriate to the inertial mass of an electron. The next step will be to repeat the experiment with positrons, for there it is expected that the effective force on the electrified particle will not be cancelled out but, rather, doubled. At this stage there is no way of knowing whether the equipment will provide a means of testing the suggestion that particles such as electrons and anti-particles such as positrons may be found to repel each other, but this is at least an intriguing possibility.

It is true, of course, that this experiment is only possible because of the way in which large superconducting magnets can now be designed. It is also true that the phenomenon which is being studied has been drawn to public attention in the most indirect way. But the way in which the experiment has been designed and carried out is a proof that the traditions of elegance in physics continue. That is something to be grateful for.

clusion is that the local cluster, as defined by the presence of B type stars, occupies a strip 200 parsecs wide and 500 parsecs long with the Sun at the leading edge of the strip and roughly 75 parsecs from the central axis.

In his analysis, Dr Clube has used a total of 113 B stars with accurate radial velocities and with proper motions which have been measured accurately. Following earlier investigators, he has sought to represent the motions of these stars by a model in

which the stars as a whole are streaming and at the same time dispersing as if from some common origin. On this basis, Dr Clube is able to calculate the most probable direction and velocity of streaming and also to infer that the stars of the local cluster would have been at a common origin roughly 37 million years ago. He points out that this estimate is uncertain but that it is also comparable with the time scale for oscillations about the galactic plane, estimated to be about 80 million years. From this point of view, it is inferred that the stars of the local cluster can have had very little influence on the dynamical behaviour of other stars in the neighbourhood.

The local cluster, defined by the B stars, is also known as Gould's Belt, after the English astronomer Gould who worked in the Argentine in the late nineteenth century. The significance of the concentration of bright B stars towards the direction of galactic longitude 160 was first appreciated by Herschel early in the nineteenth century.

Hallucinogens and Psychosis

from a Pharmacology Correspondent

HALLUCINATION provoked by drugs may not be quite the same as the perceptual distortion of schizophrenia, but the two mental disturbances are close enough to lead us to seek a link between their mechanisms. One link proposed is that, in schizophrenia, an abnormal endogenous substance (or excess of a normal one) with hallucinogenic activity is present in the brain. As the recently published symposium Amines and Schizophrenia (Pergamon, Oxford, 1967) bears witness, the likeliest place for such a substance still seems to be among the amines where the quest was started some 15 years ago by Osmond and Smythies. Hitherto, amines that are hallucinogenic-such as mescaline, bufotenin and N,N-dimethyltryptamine—have not been indubitably detected in the human body, whether schizophrenic or normal, whereas the amines which are present—such as dopamine, 5-hydroxytryptamine and 3,4-dimethoxyphenylethylamine—have not certainly been found to induce hallucinations. If the report of Tanimukai et al. (Nature, 216, 490; 1967) is confirmed, however, this impasse may now have been ended by the detection of bufotenin in the urine of all of six schizophrenic patients (three paranoid and three catatonic) and in one of four mental defectives.

In the search for an abnormal amine in schizophrenia, much interest and controversy has centred on the pink spot, first observed in paper chromatograms of the urine of schizophrenics by Friedhoff and Van Winkle (Nature, 194, 897; 1962). That this spot contains 3,4-dimethoxyphenylethylamine has just been confirmed by Creveling and Daly (Nature, 216, 190; 1967), although its chief constituent is probably p-tyramine (Boulton et al., Nature, 215, 132; 1967). The further finding of Creveling and Daly that the pink spot in the urine from two schizophrenic patients contained at least seven different compounds shows how far we are still from fully understanding the spot. The scrutiny of amines in the urine may now be expected to intensify.

Progress in this field might be quicker if a completely reliable means of detecting and measuring an hallucinatory effect in laboratory animals were available. The difficulty of knowing whether a measurable response of animals corresponds to a psychic effect in

man was illustrated in the recent identification by Isbell and his co-workers (*Psychopharmacologia*, 11, 184; 1967) of $(-)\Delta^9$ -trans-tetrahydrocannabinol (Δ' 3,4-trans-tetrahydrocannabinol by another notation) as an active principle of cannabis. In dogs, this compound and cannabichromene both caused ataxia, which was thought to be a good indication of cannabis-like activity; but, in human volunteers at Lexington, only the tetrahydrocannabinol induced sensory distortion and euphoria resembling those of cannabis.

One wonders whether any of the animal tests proposed to predict hallucinogenic activity in mansuch as those of Jacob et al. (Med. Exp., 7, 296; 1962), of Lipman et al. (Arch. int. Pharmacodyn., 146, 174; 1963), of Knoll et al. (Arch. int. Pharmacodyn., 159, 442; 1966), of Smythies et al. (Psychopharmacologia, 10, 379; 1967) or of Corne and Pickering (Psychopharmacologia, 11, 65; 1967)—would have given the correct answer with the two substances from cannabis. Although this question is unanswered, there is no doubt that, at least within a group of compounds, good correlations can be found between an animal response and hallucinogenicity in man, although no single test so far devised has been shown to predict hallucinogenicity in every group of compounds known to possess that property. The mouse head-twitch test of Corne and Pickering, for example, though usually correlating well with the human findings, fails to predict the hallucinogenicity of drugs of the nalorphine type.

Such tests are therefore likely to be most useful when applied to a single group of compounds, several of which are of known hallucinogenic activity in man. Even so, proof of hallucinogenicity in new compounds must rest on experiments in man himself. These experiments should be strictly controlled and supervised by a clinical pharmacologist; but a portion of the youth of today is so hungry for hallucinations that it may provide, unasked, a rough guide to the effects of some of the new compounds in man.

Since the fashionable hallucinogen STP is a methoxy-amphetamine derivative (Snyder et al., Science, 158, 669; 1967), we can take the finding of Smythies and his colleagues (Nature, 216, 128; 1967)—that 3,4-dimethoxyamphetamine and 4-methoxyamphetamine disrupt the behaviour of rats as mescaline does—to mean that two further potent drugs have now been added to the list of hallucinogenic amines. Unless evidence can be got that schizophrenics are able to synthesize one of these methoxyamphetamines, neither compound is likely to prove the missing piece of the jigsaw; but either may well provide the true explanation of how the psychosis of amphetamine addicts develops.

Strength of Ordered Alloys

How does the crystallographic order in alloys affect their mechanical properties? Professor R. W. Cahn, of the Department of Materials Science at the University of Sussex, considered the problem in a lecture to the London Metallurgical Society on November 2.

Professor Cahn began by drawing a contrast between alloys, such as Cu₃Au and Ni₃Fe, in which ordering of the constituent atoms is not associated with any change of symmetry, and alloys such as CuAu and CuPt, in which ordering leads to a change of symmetry and also to a substantial change of shape and dimensions of the unit cell. These two categories behave quite

differently, but share the unique property that the influence of atomic configuration on physical and mechanical properties can be separated from the influence of variables such as composition, grain size, etc.; and the configuration is changed when an alloy is heat-treated to order it. By quenching out different states of order and testing at ambient temperature, even the influence of temperature can be separated out.

A substantial body of research on several alloys of the first type had established that the flow stress is a function of degree of order, reaching a maximum at intermediate degrees of order. Numerous interpretations had been advanced to account for this maximum; perhaps the most attractive, Professor Cahn thought, invoked the observed pairing of dislocations to form "super-dislocations" linked by a ribbon of imperfectly ordered alloy. The ribbon broadens as order diminishes and eventually the dislocation pairs disperse; this stage is held to correspond to maximum strength. Other features discussed included the work-hardening capacity of ordered alloys, their strain-ageing behaviour (which revealed a negative correlation between order and rate of recrystallization of a cold-worked alloy), their creep (revealing a pronounced anomaly at the temperature at which order finally disappears) and their fatigue and fracture properties. These last were rationalized in terms of the influence of order on the morphology of plastic slip in alloys. Order totally inhibits cross-slip, which has a crucial influence on both fatigue and

The second category of alloys—those which change symmetry on ordering—have been much less investigated. Professor Cahn described a recent study by V. S. Arunachalam and himself on the mechanical properties of CuAu, which transforms from cubic (disordered) to tetragonal (ordered). A single cubic grain acquires a system of microstrains because of the shape changes associated with ordering in the various microdomains into which the crystal decomposes. These microstrains produce hardening; if they become too large, spontaneous fracture may also ensue. Strainageing behaviour is quite different from the first category of alloys. A strange consequence of the change of shape of the unit cell is that a very small elastic stress applied during ordering can completely change the morphology of ordered domains and alter both the dimensions of the entire sample and also its mechanical properties. In Professor Cahn's view, this novel form of 'superplasticity', and indeed the behaviour of this class of alloys generally, deserves more attention than it has had in the past.

Bacteria and Plastics

from a Correspondent

THE Microbiology Group of the Society of Chemical Industry held a meeting on Thursday, November 2, on the Biodeterioration of Rubbers and Plastics. First Dr G. H. Booth and Mr J. A. Robb of the National Physical Laboratory read a joint paper on the bacterial degradation of plasticized PVC, describing their experiments with five PVC polymers, 13 plasticizers and two stabilizers. Films were buried at 22°-25° C in neutral soil which had been enriched with bacterial cultures from a variety of sources. When diiso-octyl phthalate was used as the plasticizer and white lead as

stabilizer, the change in properties after burial was relatively small for all fine polymers. One of the homopolymers was then combined with each plasticizer in turn, using white lead as a stabilizer, and finally the series was repeated with a cadmium stabilizer. When di-ammonium phosphate or a chlorinated hydrocarbon was used as plasticizer, the change in properties was less for the cadmium-stabilized film than for the lead-stabilized film, suggesting that the cadmium compound was more toxic than the lead compound towards the bacteria. The fact that the degree of attack depended on the plasticizer suggested that it was this which was being consumed in all cases.

Dr S. H. Morrell of the Rubber and Plastics Research Association, Shawbury, Shropshire, gave a general paper reviewing the effects of micro-organisms, principally fungi, on rubbers and plastics. He reminded his audience that rubbers and plastics were often complex materials containing inorganic as well as organic additives, and suggested that reported attacks might well be confined to consumption of these additives rather than destruction of the polymer. In some cases the attack had been exaggerated, incidents of "failure" being quoted when the material was well able to give good service for some considerable time.

There was a detailed description of the various rubbers and plastics, together with comments on the chemical nature of the material and possible reasons for its attack or otherwise by micro-organisms. It was concluded that evidence of attack was sometimes confused and contradictory, and in some cases it was necessary to distinguish between actual attack and growth on the surface of the material. It could not be said that only naturally occurring polymers were attacked, nor was it possible at this stage to say which chemical groups in each polymer were susceptible. The meeting concluded with a vigorous discussion on both papers.

Simulated Growth and Morphogenesis

from our Microbiology Correspondent

THE behaviour of complex systems, most prominently illustrated by those of air and road traffic control, can be analysed effectively by simulation techniques. The usefulness of such studies is determined by the number of parameters of the system which can be programmed. In biological systems the parameters of growth and morphogenesis are inadequately defined and complete simulations are not feasible. Biological patterns can, however, be studied with computers and two recent papers are sound advocates of this approach.

În this journal Cohen has reported attempts to simulate two-dimensional branching patterns of the type produced by surface cultures of fungi and the vascular systems in leaves (Nature, 216, 246; 1967). Programmes were written for each class of pattern to be simulated, the rules being determined from acceptable hypotheses of the natural system concerned. Cohen limited his analyses to patterns based upon apical growth and sub-apical branching and examined the introduction of four types of effect: (1) varied growth parameters in branches of different rank, an effect producing hierarchical organization; (2) changing parameters during the course of growth; (3) influence of branch length on the extent of growth and branching; and (4) local disturbances in the growth domain. The

latter effect induced the most complex patterns which were analogous to phenomena such as antibiosis and local concentration of nutrients in the growth of fungal colonies.

The second report comes from Dr George Ware of the University of Bristol (J. Theoret. Biol., 17, 91; 1967), who has simulated bacterial growth in submerged culture on a digital computer. Here a programme was compiled which allowed the simulation of mixed cultures and which could accommodate the appearance of spontaneous mutants and contaminants. programme was written assuming that a proportion of the cells were non-viable and that the rate of death was dependent upon the half-life of the organism, the total population and the M-concentration (a strain constant defined as the yield per unit volume of medium). Information of the following kinds was required in the programme: (1) strain parameters such as doubling time (t_d) , yield constant and half-life; (2) culture parameters such as substrate levels and incubation times; (3) specific growth rate and factors modifying it; and (4) the probabilities of forward and backward mutation rates. The killing of cells by antibacterial substances was assumed to be controlled by the strain sensitivity and the concentration and activity of the substance. Ware has used his programme to study the lag phase, simple and complex cultures and the production of mutants. Duration of the lag phase was varied by manipulating the length of the delay array, that is, the delay response to the substrate. With a delay array length of one location, lag was absent, but tenfold increases extended the lag phase to 26, 202 and 1,920 min respectively. In the latter case (1,000 delay locations) the population had nearly attained its maximum size before the theoretical growth rate was reached. The behaviour of mixed cultures was tested by co-inoculation of a bacteriocide-resistant strain $(t_d=45 \text{ min})$ and a bacteriocide-sensitive strain $(t_d=$ 20 min). Following the lag period, both strains grew exponentially for 8 h until growth limiting conditions became established. Subsequent addition of an antibacterial agent produced a decline in the growth of the former strain while the growth of the resistant strain recommenced and continued until the substrate was exhausted. The aptness of assumptions made in programme compilation is criticized by Ware and, despite certain invalidations, well defined growth patterns can be simulated by considering relatively few parameters. That we may predict bacterial behaviour in mixed systems and responses to quantitative and qualitative changes in the growth medium and the population per se is likely to stimulate great interest in both academic and commercially orientated laboratories. At this time, when growth parameters are only partly documented, there is no thought of the computer replacing the pilot fermenter. Eventually, however, we might anticipate wide use of culture simulators to test theoretical schemes before taking up the commitments of laboratory trials.

Myosin Revealed

from our Molecular Biology Correspondent

THERE has for some time been conflict in the field of muscle biochemistry about the nature of the myosin

The thick filaments in striated muscle are molecule. known to consist essentially of this protein, which is responsible for the hydrolysis of ATP, and its interaction with actin is central to the process of muscular contraction. It has been known for some time that myosin consists of a long shaft (some 1400 Å by 20 Å thick), with a globular head at one end, which is the seat of the ATPase activity and of the actin-combining sites. The dispute has centred around the number of long polypeptide chains contained in the myosin molecule—two on one view and three on another. To decide between these is important, for it must be supposed also to define the number of active sites, and whether the shaft (known to be fully a-helical) is a two or three stranded supercoil.

The question seems now to have been resolved by new observations with the electron microscope, and the protagonists of the three-chain model would seem to have been vanquished. Slayter and Lowey (Proc. US Nat. Acad. Sci., 58, 1611; 1967) show electron micrographs of rabbit myosin molecules in which it is for the first time apparent that there is not one head at the end of the molecule, but two. This result was achieved by the technique of rotary shadowing—that is by rotating the specimen during the shadowing process: in earlier work, the outline of one head was always obscured by, or merged into, the shadow of the other. The conclusion is thus almost inescapable that there are two similar chains in the molecule, and this symmetry must be regarded as an important clue to the mechanics of muscular contraction.

Slayter and Lowey have also clarified the relation between the major proteolytic fragments of myosin: tryptic digestion of the native molecule leads to the well known light meromyosin (shaft) and heavy meromyosin (head and some shaft) fragments. In this cleavage, about one-third of the shaft is present in the heavy fragment. The products of further cleavage, subfragments 2 and 1, of heavy meromyosin are now recognized as the portion of shaft and separated single heads respectively. In the electron microscope, heavy meromyosin is indeed seen as a truncated myosin, and subfragment 1 as isolated globules. (It is to be noted that these retain their ATPase activity.)

Although this work settles the gross structure of the myosin molecule, there remains the problem of the mysterious fragments of low molecular weight which are liberated on denaturation and without proteolysis. Several workers have reported that these components constitute perhaps 15 per cent of the total myosin In the most recent study, Locker and Hagyard (Arch. Biochem., 120, 454; 1967) have found that on disruption of the myosin structure by chemical modification, three separate protein components of molecular weight about 17,000, 19,000 and 20,000 are released. Two of these species originate solely from the "heavy" end of the myosin—that is to say they must be present in the heads. Because it has so far been possible to release the fragments only under conditions leading also to loss of activity of the myosin, it is not possible to assert whether they are functional parts of the whole. It has not yet been properly established whether these fragments of low molecular weight in fact form an integral part of the myosiu molecule, or are merely strongly bound extraneous components.

Self Assembly of R17

from our Cell Biology Correspondent

Earlier this year (see Nature, 214, 1074; 1967) Sugiyama et al. reported that incubating MS2 phage coat protein with MS2 RNA produces phage-like particles. Although these self assembled particles cannot be distinguished from authentic phage in the electron microscope, they are not infectious and sediment at 70S instead of 80S. Since then Hohn (Europ. J. Biochem., 2, 152; 1967) has done similar experiments with the closely related phage fr and obtained essentially identical results. These noninfectious particles, assembled in vitro, closely resemble defective non-infectious particles produced in vivo during replication of certain amber mutants (A cistron or Sul mutants) of fr and the closely related phage f₂ and R17. Apparently, both types of non-infectious particle are defective because they lack a minor protein component, the A protein specified by the A cistron, which is present in intact infectious RNA phage (Nathans et al., 1966; Argetsinger Steitz, 1967) and somehow ensures either the correct encapsulation of the phage RNA or the absorption of the phage to E. coli hosts or both.

The obvious experiment was to add this missing A protein to the coat protein/phage RNA mixture and see if infectious phage are reconstituted. The great difficulty, of course, was isolating enough A protein; each intact phage probably contains only one molecule of A protein and this has to be separated from the 180 coat protein molecules. Argetsinger Steitz has done this; the A protein apparently has a molecular weight of about 35,000, and although it is highly insoluble in aqueous buffers enough has been obtained to do the self assembly experiment, and Roberts and Argetsinger Steitz now report the successful in vitro assembly of infectious R17 phage (Proc. US Nat. Acad. Sci., 58, 1416; 1967).

When A protein is added and dialysed with a mixture of R17 coat protein and RNA, the yield of infectious phage increases by a factor of several hundred. The titres of infectious phage obtained are impressively high, up to 1.3×10^7 phage/ml., although the efficiency of reconstitution is only 2×10^{-6} . The maximum yield of infectious phage is obtained when one A protein molecule per phage RNA molecule is added: more A protein does not increase the yield. Two factors probably account for the low efficiency of assembly of infectious phage. First, RNase almost certainly contaminates the isolated components, and this would degrade the RI7 RNA before it is incorporated into particles. Second, the protein and RNA must necessarily be subjected to harsh treatments during isolation and are probably partially inactivated as a result. When the complete assembly mixture was analysed on a sucrose gradient, the bulk of the reconstituted particles were 70S defectives, but the majority of the infectious particles sedimented at 80S like wild-type phage. Mild RNase treatment of the reaction mixture completely removed the 708 defectives leaving only the 80S infectious particles, but even some of the infectious particles are sensitive to RNase whereas normal phage is completely resistant. Clearly some of the reconstituted phage, though infectious, are not quite normal: it seems probable that these arise because some of the protein incorporated is partially damaged

and does not protect the RNA from degradation by RNase.

Despite these qualifications, this experiment is the first in which a phage has been reconstituted in vitro, albeit at low efficiency, from two species of protein and a nucleic acid, and this has considerable implications for ideas of organelle self assembly. Furthermore, the experiment provides definite proof that the A protein is a necessary constituent of infectious RNA.

No Life on Life Origins

from our Special Correspondent

THE first public meeting on November 2 at the opulent new premises of the Royal Society was a disappointing affair. As Sir Robert Robinson said when introducing the morning session, the subject, "Anomalous Aspects of Biochemistry of Possible Significance in Discussing the Origins of and Distribution of Life", was particularly fitting for the occasion because it provided an opportunity for the sort of speculation and intellectual curiosity which had excited the founders of the Royal Society. In the event, the speakers and the audience rarely responded to this challenge. Instead, there was a series of thirty minute reviews—inevitably superficial for lack of time—of the occurrence in some biological systems of carbon, halogen, silicon and vanadium compounds and of why ATP is the universal mediation of biosynthesis. But speculation about either the terrestrial origin of life or the possibilities of extraterrestrial life was really not noticeable. The speakers, many of whom no doubt seldom view their work in this light, may have done their best, but the general discussion never came to life and was very much restricted to the here and now. The smell of the lunch being cooked in the kitchens below was, perhaps, too distracting.

In the afternoon, Professor H. E. Hinton (University of Bristol) described his experiments on suspended animation in insects which prove that living systems can survive alternate cycles of hydration and dehydration-some species apparently survive exposure to temperatures varying from below the boiling point of helium to +104° C after total dehydration. He then gave several cogent reasons for believing that life originated on the surface of the Earth rather than in a continuously wet environment, the chief one being that only in niches of rocks or dust particles, or in small pools subjected to drying, would concentrations of chemicals have become sufficiently high for macromolecules to be formed. Dr M. V. Tracey (New South Wales) then described fascinating experiments on the way stimulants of the central nervous system and anaesthetics induce ordered clusters of water molecules in bread dough, of all unlikely things. He suggested that plant alkaloids originated because of their ability to regulate cell water content and postulated a closed circulation plant. Then there was a description of an anaerobic ecosystem based on the sulphate/sulphide transformations and the possibility that such systems could well be similar to an early stage in the evolution of life after its origin. The last paper reviewed the great diversity of compromising environments which support microbial life, including a brief mention of experiments with simulated Martian conditions. The applause woke the sleepers, and after a few questions the meeting closed.

Diversification in a Government Laboratory

A year has gone since the Ministry of Aviation and the Ministry of Technology were amalgamated. What follows is an account of how one laboratory has responded.

THE Royal Radar Establishment at Malvern, the largest centre for electronics research in the United Kingdom, is still a defence research establishment. But, like other laboratories run by the Ministry of Technology, it is showing an increasing interest in industrial research. Perhaps a tenth of its effort is now directed in this way, and the defence work is also closely scrutinized to see if it could yield commercial dividends. Is this a sensible policy? The question is worth asking, because the tendency to turn military research establishments into industrial laboratories is being actively encouraged by the ministry.

The move towards civil applications at Malvern has had the official seal of approval for only a year, when it was announced that the Ministry of Aviation was to be merged with the Ministry of Technology. In February of this year, the RRE set up a special industrial unit at Malvern to speed the process—the Industrial Applications Unit, directed by Mr B. W. Oakley. This new unit is the channel through which industrialists can gain access to the establishment, which offers them a consultative service with experimental and research backing. The service stops short of engineering development for production, which is left entirely to industry. So far the developments of the unit show more promise than commercial success, but it is early days yet, and a number of the products may well have a future.

In the radar field, use is being made of the Gunn oscillator, which enables transmitters of radar sets to be reduced in size. The oscillator consists of a slice of the semiconductor gallium arsenide, deposited as an epitaxial layer on a substrate of the same substance. Because of the electrical properties of the material, it acts as a source of microwaves when a potential is applied between the epitaxial layer, which acts as a cathode, and the substrate, which acts as an anode. This dispenses with the need for klystron tubes and bulky power packs, since the gallium arsenide slice is very tiny, and the device operates at a voltage of 6-12 volts. The oscillator, invented in the United States in 1963 by J. B. Gunn, has been used at RRE in a variety of small radar sets. These can be used as burglar alarms, portable speedometers, or very accurate radars for short range work. The Gunn effect can be used to produce very short bursts of microwaves, which enables the small radar sets to distinguish distances as short as three feet at a range of fifty yards. This may be of importance in harbour navigation in dense fog.

Other radar developments look far more sophisticated and more distant than this. One group at Malvern is working on the integration of radar with computers, and is developing systems which can function both as general surveillance or as horizon scanning radars. Another military technique, the use of infrared detectors, is also expected to have civil applications. The detectors can be used in a variety of ways—as flaw detectors in such things as brake linings, or for the detection of breast cancers or circulation deficiencies such as varicose veins. Alternatively the detectors can be used as a form of aerial photography, and provide information about sewage outfalls, or the flows of heated water from power stations. Since the possibilities of the technique were first made public six months ago, more than 100 requests for information have come in from industry.

Malvern also boasts a powerful computer group, entirely devoted to development of software. Two main projects are in progress—the development of a simple language for simple computer applications, and the computer-aided

design of micro-electronic circuits. Another development of computers is in the supply of information in the form of displays on a cathode ray tube. This can be particularly valuable to air traffic controllers, who have to handle and correlate large quantities of data, but there is no reason why displays should not be applied to more mundane computer applications such as stock control. By the use of touch wires—essentially switches set into the face of the CRT—the operator can achieve some sort of interaction with the machine, and call up from the data stores such information as he requires.

All these developments are interesting, and possibly profitable. It seems clear that industry has been sniffing round Malvern with increased enthusiasm in recent months. What is not clear yet is whether this inversion of normal industrial policy, with market research following rather than preceding research, can ever work. For one thing, it is likely to prove an expensive way of doing research, both in time and in manpower. Unless industry can tell the RRE exactly what it wants, the laboratory is likely to produce ten developments for every one it manages to sell. An industrial laboratory with this sort of record would soon be shut down, but Malvern will never be subject to the full rigour of industrial competition.

This is really the fundamental problem. It is agreed that one of the problems of British industry is the long gap between discovery and commercial application. As Dr Glazier, Director at Malvern, puts it—"It is well known that the development cycle (research to in-service) for modern systems for defence can extend over many years, and civil systems of any magnitude are not likely to be much different". But they must be different if British industry is to shake off its unhappy reputation for getting to the answer too late. On the face of it, it seems unlikely that a division of responsibility between research and production will help. It may well be a positive hindrance. Without in any way maligning government establishments, it is certainly true that they lack the commercial drive which is a characteristic of the best industrial laboratories.

At Malvern itself, there is marked enthusiasm for the new approach. Dr Glazier draws a parallel between Britain's wartime position and her industrial position now, and hopes that RRE has as significant a part to play in the second as it did in the first. Mr Oakley says that enthusiasm is such that it has become difficult to find the men and the money to do all the things industry would like him to do. "But the important effect," he says, "has been to the defence work. The attitude is now completely different." Dr Glazier makes the same point—"We're trying hard to ensure that defence work useful to the economy is not overlooked." This is fair enough—as long as there is a need for defence research, it should be supported, and any industrial benefits can be considered as happy but unplanned accidents. Real industrial research is a very different problem.

Much will depend on the detailed arrangements. Although in the short term the industrial applications unit will be handling projects begun under defence contracts. ultimately it will have to initiate new projects intended solely for commercial development. When this happens it will be important to insist that industry is involved right from the start, and preferably on a sponsorship basis, so that it has a financial interest in seeing the project through quickly. And it may be better if Malvern restricts itself to research of a fairly basic kind—the supply of critical data, for instance—if it is to avoid problems of commercial secrecy.

Promise and Problems of Modern Science

by C. F. POWELL In his concluding address at the symposium on "Perspectives of Nuclear Physics, Elementary Particle Physics, Radio-chemistry and Nuclear Chemistry", held in Warsaw in Cctober to mark the centenary of the birth of Marie-Curie, Professor Powell discusses some of the problems of the advancement of science in the future.

When I was invited to give this concluding address, it was suggested that it would be appropriate if I spoke briefly on the perspectives of the subjects to which Maria Sklodowska-Curie gave such a great stimulus and the problems which their rapid development raises for the future; on the influence of fundamental research. particularly in particle physics and the manifold applications of radioactivity, on the general development of science and human culture; on the importance of the international co-operation which it engenders; the promise of science for economic development; and the problems raised by the increasing resources in men and money necessary to carry it out. These subjects have been widely discussed during the past few years, and Professor Amaldi and I contributed to them at the meeting of the Council of the European Centre for Nuclear Research at Geneva held to mark the tenth anniversary of the foundation of that organization. Much of what I have to say today is complementary to what was said then. Let me begin by summarizing only briefly the main arguments which we developed on that occasion.

Developments in Particle Physics

I suppose that most people would now agree that one of the outstanding features of our times is the headlong advance of science and technology and that it is in these fields that the human creative intelligence today finds one of its chief means of expression. A country not involved in some aspects at least of advanced science tends to be outside the main stream of human development with the most serious consequences for its intellectual life and its productive power.

Nuclear and particle physics, and the associated subjects which have been reviewed at this symposium, are among the main growing points of science and are concerned with our deepest penetration into the structure of the material universe. From the time of classical antiquity it has commonly been assumed that there would one day be an end to the process of delving deeper into the nature of matter. But such a position can no longer be asserted and it is now not unreasonable to suppose that there are no "atoms" in the o'd Greek sense of the word—"that which cannot be cut". The contributions to this conference have brilliantly illuminated the immense promise and vitality of the subject.

The developments of the past decade, the discovery of large numbers of particles, less stable but not less significant than the electrons, protons and neutrons of our familiar world, and their arrangement into ordered families in a way so reminiscent of the Mendeleef Table of a hundred years ago, demonstrate conclusively that we are entering fundamentally new domains. I recently recalled the astonishing remark made by Lenin in Empirio-Criticism in 1912, when the electron was the only known elementary

particle. At a time when the whole scientific world tended to think of fixed unchanging particles he said: "The electron is inexhaustible."

The great generality of these advances and their profound implications give us confidence that the subject will continue to be one of the principal areas of advance in fundamental science for many years to come; and that the new picture of the constitution of matter which will be established will have resounding effects on the whole of natural philosophy.

In response to the challenge of the subject, and its great promise, large resources in men and money are now being devoted to the national and international institutions housing the great accelerators and associated equipment indispensable for present studies in particle physics. The most powerful states are still able to build great machines from their own resources and there are substantial advantages to the physicists of any country in having their own accelerator. But for smaller states it is difficult to find the means in men and money for the construction and effective exploitation of machines of this magnitude and a widely ranging collaboration has been established in Europe at CERN, Geneva, which has been eminently successful in constructing and running the CERN 28 GeV proton-synchrotron; and this institution serves as the active centre for the consideration of the 300 GeV machine which would meet the needs of western Europe during the last quarter of this century, and provide complementary facilities to the 70 GeV machine at Serpukhov and the 200 GeV accelerator in the United States.

Changes in the Style of Work

It is difficult for a scientist brought up in the style and traditions of thirty or forty years ago to visualize, without seeing them in action, the immense change in the method of work which these institutions represent. They involve thousands of people, and are the embodiment of the most sophisticated technology, of the most beautiful precision engineering, of the most advanced science, and they pose most stringent problems in planning and management.

Sixty years ago, when the Curies were at the height of their powers, and even thirty or forty years later, research in particle physics still had all the charms of individual creation. A man or woman might still have the idea for an experiment, construct the apparatus, with the assistance perhaps of a good mechanic, make the observations, and write an account of the work. It was still even possible to conceive of an experiment and carry it out, with materials immediately to hand, in the space of a few weeks. An artist enjoys similar advantages, and scientists are very reluctant to abandon that close and satisfying method of work until the growing complexity of the subject and the inescapable sophistication of the

methods indispensable for significant investigation force them to do so.

During the 1930s, we began to see a different pattern emerging with the introduction of the particle accelerators. The change was greatly stimulated by the development of nuclear energy for peace and war, the experience gained by a whole generation of physicists of operations on an industrial scale, and the necessity of working together in large teams.

So it was in particle physics that we first saw something of the tone of the science of the future, of the style of work which we may expect to prevail in more and more branches of science as the techniques develop. But what is the justification for such enterprises which make great demands on money and scarce manpower?

Promise of Modern Science

It has always been difficult to assess the implications of fundamental advances in science in their early stages, for we fail to see beyond the horizons of our own times. There is a remarkable passage from a lecture made by Clerk-Maxwell a hundred years ago: "For us who know only the spirit of our own age, and the characteristics of contemporary thought, it is as impossible to anticipate the general tone of the science of the future as it is to predict the particular discoveries it will make. Experimental science is continually revealing to us new features of natural processes and we are thus compelled to search for radically new forms of thought for their description."

It has often been remarked that it took 50 years for Faraday's experiments in electro-magnetism to reach practical fruition. Another example is provided by the developments of the 1920s and early 1930s which saw the birth of quantum mechanics and the incorporation within its framework of the theory of relativity. The concepts which were then introduced seemed strange and esoteric at the time, and of little practical importance; they have now pervaded the whole of science and are of fundamental importance for whole industries. It is similarly difficult for us to assess the consequences which will flow from the developments of recent years. They will surely be very profound, but all our experience suggests they will far exceed our most daring expectations.

It is sometimes said that, for the practice of the future, the deeper penetration on which we are now engaged is unlikely to have great implications since the processes are remote from those which are the most significant for our ordinary experience. This seems to me to be too narrow a view. Even if they do not contribute greatly to developments of industry as we know it, and I think they will and do, it is one of the functions of the most sophisticated science to give rise to radically new industries, undreamt of within the framework of our present perspectives.

Taking into account the recently discovered astronomical objects such as "quasars" and "exploding galaxies" in which there are prodigious sources of energy, estimated to be sometimes as great as 1062 ergs, which cannot be accounted for in terms of conventional nuclear processes, and the most suggestive regularities among the newly discovered particles, who would assert that in a hundred years time, if we do not destroy our whole civilization, we shall not have understood and mastered new sources of energy immensely more productive than nuclear sources of power?

Or who would set a limit to the perspectives which are emerging from the tremendous advances coming from the application of radioactivity to chemistry, medicine and biology? If we fail to think imaginatively about the possibilities arising from the advancement of science, and the means to realize them, who will? Who can?

But our present knowledge in many of these new fields is still rudimentary, like that in the early days of discoveries about electricity when the main facts were the twitching of a frog's leg under electrical stimulus, or the lightning discharge. Who could then have foreseen that such phenomena, so completely remote, so it seemed, from practical application, would one day provide an indispensable element for the whole of our civilization?

Of course it is in the nature of fundamental discoveries that they cannot be foreseen and that we can have no assurance of all the consequences which will flow from them. The new feature of our situation is that the resources required by science are substantial both in men and treasure. We should be careful to distinguish what is assured and what can be reasonably anticipated in making a case for great new scientific enterprises and be prepared continually to assess their significance and to run them down if our hopes seem unlikely to be realized. But if we fail to act with imagination and boldness, very grave consequences will certainly ensue.

At the present time the great states devote about three parts in one thousand of their gross national product to fundamental science, and this fraction is increasing. But how dominant a part will science play in our culture in 100 years time? It has sometimes been remarked that, starting at present levels, and, if the proportion of our resources going into fundamental science doubles as at present every 8 or 10 years, then in 100 years time there would be nothing left for anything else but fundamental science. Some scientists have suggested that the proportion spent on fundamental science should level off at about six parts in one thousand of the GNP; others, that in 100 years we may devote 50 per cent of our resources to it in a situation where, as in the institutions supporting the accelerator, the distinction between science and technology has largely disappeared. It is difficult to find a firm basis for distinguishing between these very divergent predictions, but I would think it most unlikely that in 25 years time we shall keep expenditure down to 1 per cent of the GNP.

But the fruits of profound scientific advances are not confined to the material benefits which arise from them more or less directly in the form of radically new industries. The whole of science and technology, theory and practice, constitutes a most complex organism with innumerable concatenations and we shall need all the wisdom we can muster to ensure a balanced development. But, in our era, the history of science demonstrates the indispensable role, in the advancement of science as a whole, of our basic understanding of the constitution and interaction of the elements of matter at different levels according to the sophistication of our understanding. It seems most unlikely that a real understanding of the new realm in the hierarchy of "elementary particles" which we now seem to be entering can fail to have a similar significance for the general body of the science.

Again, it is an essential feature of the institutions supporting the great national and international accelerators that they work in the most intimate collaboration with the scientists in our universities and other institutions of higher learning. This is of great value to the international institution, but it also has the consequence that the tone of the university departments of science involved, and the quality of the thinking and teaching within them, are stimulated by the fact that they are peopled by men and women engaged in work at the frontiers of knowledge whose imagination is, in a phrase of Bacon's, "being stretched and enlarged to take in the image of the universe as it is discovered". This stretching and enlarging process produces confident and lively minds, capable of inspiring the youth with their own enthusiasm for science and technology.

So I would say that the justification for great expenditures on fundamental science has three aspects. First, because of its effect on the general body of science and on our scientific world outlook; secondly, for the practical consequences which flow directly and indirectly from the advances in science generally in the form of radically new industries and improvements in current practice;

and, thirdly, from the fact that the pursuit of knowledge is an essential element in contributing to a healthy tone in our universities and institutions of higher learning; that this can only be ensured if the people in them are engaged in exacting investigations on the frontiers of knowledge, and is of crucial importance for our whole culture.

Difficulties arising from the Changing Methods of Science

It is sometimes said that the science of 50 years ago was the science of the "pre-historic" scientific epoch. It is a phrase which makes me very uneasy. It implies too little acknowledgment that we see farther, because we, too, stand on the shoulders of giants. It is of course true that there are great advantages in having sufficient resources. Madame Sklodowska-Curie, in a discourse at the Sorbonne in 1924, remarked: "Il est vrai que la découverte du radium a été faite dans des conditions précaires, et le hangar qui l'a abritée apparaît revetu du charme de la légende. Mais cet élément romanesque n'a pas été un avantage: il a usé nos forces et retardé les réalisations. Avec les moyens meilleurs, on eût put réduire a deux ans les cinq premières années de notre travail et en atténuer la tension—l'experience du passé ne doit pas être perdue pour l'avenir."

But while it is a great advantage to have the tremendous resources which are now available, it is not a virtue, and we shall be judged by what we achieve with them—by the quality and tone of our inspiration. We are in a situation where we can afford to be neither complacent nor arrogant.

I see the science of the past 70 years as a kind of golden age and our principal task to ensure its continuation. In the past, periods of the highest achievement have been short and precarious. The principal figures are themselves unique; and so also is the complex of situations and influences which make up the historico-social background. In our times, if science and technology have a tremendous impact on our societies, it is no less true that they are dependent on the general tone of the society in which they exist, on prevailing attitudes towards science, on the esteem in which it is held. And there are a number of disturbing signs of the time which should teach us not to take for granted an automatic progression. The provision of adequate resources is not the only thing necessary for distinguished scientific work. It has long been recognized that it also requires great determination, passion and imagination. There is an illuminating passage from Erasistratus: "Those who are altogether unaccustomed to investigation are, at the first exercise of their intelligence, befogged and blinded and quickly desist owing to fatigue and failure of intellectual power, like one who without training attempts a race. But he who is experienced in making experiments, twisting and turning and worming his way through, does not give up the search, I will not say day or night, but rather his whole life long. He will not rest but will turn his attention to one thing after another which seems relevant to his problem, until he arrives at the solution.'

This passage characterizes the kind of intense enthusiasm which has always been the spur to imaginative scientific work, and it is an attitude we should be concerned to preserve in the greatly changing circumstances of our times. It is not only essential for the advancement of science in the era of great scientific enterprises but the best receipt for a humane, productive and satisfying life. It ought to be an aim for the industry of the future. But great science can never prosper without it and there are some dangers that we shall lose it. I see a great danger that science is tending to become dehumanized.

There are, in the first place, though they are not the most important factors, the difficulties arising from the inescapable transformation in the scale of operations in the most sophisticated sciences and the quite new demands on scientists which follow from them. They are required to work as members of a team, for long periods away from their homes and families, and they commonly play only a modest part in a large enterprise the nature of which often imposes a severe discipline, long hours, careful and relastic planning and a strict adherence to a determined time-table.

We have already seen a similar transformation on the passage from handicraft to factory production and modern large-scale industry. There it often has the consequence that a factory operative finds no outlet for his creative imagination in his work, and his real life begins only when he is relieved of the tedium of labour. The analogy between modern science and industry should not be pressed too far, for in science we rarely do things twice in the same way, but certainly such an attitude is incompatible with penetrating scientific work.

It may be remarked that it is a problem which has been overcome in the past. The building of the Parthenon made relatively greater economic demands on Athens than do large scientific enterprises on our own society. If you make large-scale drawings of the Parthenon and try to duplicate it, you get a building, but one manifestly lacking in genius. The original is in effect a gigantic work of sculpture and the subtlety of line is lost even in geometrical drawings on the largest scale. I am told that each column in the original building was in charge of a master mason who, with his artisans, worked on it for about a year. It is clear that they understood the essential place of what they were doing for the whole enterprise; and that the work made satisfying demands on their taste and skill. L'experience du passe ne doit pas être We must maintain sufficiently perdue pour l'avenir. interesting and challenging conditions of work in our scientific enterprises to produce really creative results.

In the great institutions for particle physics we seem at present to be succeeding, for the subject continues to attract a growing number of the best of the young people who devote themselves to science and this is living testimony to the promise and vitality of the subject. The Parthenon was built before that fatal division between the architects and builders had come about, and it is an important fact about our great scientific institutions that the planning and the execution are all in the hands of scientists. As with the Parthenon, we seem at present to be able to organize the work into groups in a way which does indeed give satisfying scope for skill and originality, and we must make sure we continue to do so.

Dangers for the Advancement of Science

But there are more serious features in our situation. First, the benevolent role of science as the instrument for human advancement, which was clearly enunciated by many of the early protagonists of science in our era, is now seriously called into question. This carries great dangers in a situation where the development of science may be limited more by the supply of gifted people attracted into it rather than by financial limitations on the available resources. There is in some countries a turning away of young people from science to what they feel to be more innocent pursuits. They cannot fail to see that, in spite of the great material benefits which have followed in the rich countries from the development and application of science, and its potentialities for good on a world-scale in the future, there is little indication that these possibilities are being realized. On the contrary, the rich countries are becoming richer and the poor poorer: not only in nutrition and technology, but in science itself.

Far from becoming the great creative element in a new world culture, science is tending to be more and more confined to the scientifically advanced states and this tendency is reinforced by the migration of substantial numbers of the most gifted of the youth, from their own countries, where they are indispensable for its advancement, towards the richer countries where alone can be found the means for significant investigations in the subjects of their choice. And whereas the developments in the poor countries are slow and halting—indeed, we hardly understand how to give aid effectively—a very large fraction of the body of science in the advanced countries, backed by immense material resources, is engaged in the production of armaments and an increasing development of more and more lethal weapons of mass destruction.

These tendencies apply unequally in different countries, but unless effective steps are taken to counteract them they will be very damaging for the advance of science in the future. In the interest of science itself, therefore, not to speak of wider and even graver implications, it is important that some scientists at least, and the more the better, should show themselves to be more than narrow specialists indifferent to the consequences of their discoveries, and should actively contribute towards resolving some of the grave and profoundly difficult problems raised by the headlong advancement of science, which hang like a thundercloud over everything we think and do, by giving some of their time and energy to their resolution. If we do not secure the peace of the world our whole societies are in jeopardy, but it is possible for science to lose its inspiration even without a general war with nuclear weapons.

It is unnecessary for me here to labour another point; that, in the most general sense, fundamental science and technology are indispensable elements in our culture and that in our times it is not sufficient for an educated man who aspires to be an administrator, or to occupy a position of power, to be well acquainted with the humanities and the fine arts only. But in some countries science is in fact held in little regard and such a point of view is tacitly assumed and sometimes even explicitly stated. It is of crucial importance that all over the world science shall be cultivated as a great instrument for human advancement; that its place in our educational systems and in our societies generally shall be strengthened. In many countries, including my own, the great majority of the population gain little acquaintance with science in the schools and it is almost outside the common culture.

There is a final point. I have spoken of the losses associated with the migration of young students from poorer to richer centres. Even more serious is the fact that, in an era where we need all the intelligence we can find, many potentially bright intelligences are being destroyed, especially in the early years of life, even in relatively well-to-do states. In Britain, for example, it is estimated that the intelligences of something like 30 per cent of the children will never be cultivated because of the social conditions in which they live. A school inspector recently stated that a large fraction of the children under 5 entering some schools are already conditioned not to listen because in their homes most of the communication with their parents is in the form of admonition or invective. In many countries where poverty prevails and parents are under greater stress, the proportion must be much larger.

Role of International Scientific Institutions

The establishment of international scientific centres can make a contribution to the resolution of some of these problems. Experience shows that when they are well organized and sufficiently independent the fact of nationality, far from raising difficulties, adds greatly to the strength of such institutions. Nothing binds men together like effective collaboration in attacking difficult and worthy tasks; and the joint effort is strengthened by the various qualities in which different nations excel.

When I was invited to make this address I was curious to see the tone of the scientific world not 100 but 300 years ago, and I found the following passage in the *History of the Royal Society of London* by Thomas Spratt, Bishop of Rochester, published in 1667.

"If I could fetch Materials whence I pleased to fashion the Idea of a perfect Philosopher, he should not be all of one Clime, but should have the different Excellences of several Countries. First, he should have the Industry, Activity, and inquisitive Humour of the Dutch, French, Scotch and English, in laying the Ground Work, the Heap of Experiments; and then he should have added the cold, circumspect and wary disposition of the Italians and Spaniards, in meditating upon them, before he brings them fully into Speculation. All this is scarce ever to be found in one single Man; seldom in the same Countrymen. It must then be supplied, as well it may, by a publick Council, wherein the various dispositions of all these Nations may be blended together..."

Let me add in parentheses that this passage seems to me to give a clear demonstration that, not to particularize, what we call national characteristics, which we tend to think of as relatively permanent, can in fact be dramatically changed in as short a time as 300 years.

Spratt might have widened his list of countries even in his own time. But the presence of many distinguished scientists at a symposium in Warsaw, coming from countries that he could hardly have included, shows that, in spite of lamentable gaps, we have indeed made some progress towards a public council which is really world wide.

Great international scientific undertakings, when well conceived and organized, can help to promote mutual understanding and sympathy among nations. They can help small states to provide stimulating conditions of work for some of their most gifted young people without promoting their emigration; and thus allow the most advanced science to be more closely integrated with their own culture. They can even arrest and reverse what we call the "brain-drain" and help in replacing it by a mutually advantageous two-way exchange.

There are encouraging signs that a wider co-operation is being established around both the national and the international enterprises. There is a concern to co-ordinate our efforts so that we match our machines to the talent available internationally, and do not waste money and man-power. In twenty years time, perhaps less, we may embark on truly world-wide scientific enterprises.

To further steps in these directions, I would like to suggest that this conference might be followed, in due course, by others of a similar kind. This symposium has been remarkably successful, and different from most others, in bringing together scientists from a very considerable range of subjects; and these wider exchanges have been of great advantage. Should it not be repeated and the scope of the subjects be made even wider?

I suppose it is impossible to see how a truly world society will be brought into being, but it is sure that it will be established, if at all, only after long experience of successful collaboration in many fields. I would like to think that it is in the sciences, where we work together so effectively and profitably, that some of the first steps in this direction are being taken and that when the two hundredth anniversary of Maria Sklodowska-Curie is celebrated in Warsaw we shall have gone a long way further. Perhaps we may hope that the institutions for particle physics, and similar enterprises in other disciplines, may lead to the creation of a great international academy devoted not only to the advancement of science on a world scale but also contributing to the establishment of a peaceful world in which the aims of science to be the instrument for promoting human welfare may be realized.

If you find this too fanciful, let me remind you that, in dreaming, we are in good company. In the same discourse to which I have already referred, Maria Sklodowska-Curie, speaking of her husband, said: "Nous savons quelle a été la règle de sa vie: C'est de continuer, quoiqu'il arrive, la tâche commencée: et, selon sa belle expression, 'faire de la vie un rêve, et faire d'un rêve une réalité'." Received October 27. 1967.

Origin of Indigo of Woad

by E. EPSTEIN M. W. NABORS* B. B. STOWE Kline Biology Tower, Yale University, New Haven, Connecticut

Although the ancient Briton's woad, from Isatis tinctoria L., has been differentiated from the indigo dye indoxyl-β-D-glucoside, from the tropical legume genus Indigofera, it has never been identified. It has now been shown to be indoxyl-5-ketogluconate and its structure is completely specified.

SINCE antiquity, in temperate climates, woad (Isatis tinctoria L.) has served as a source of the blue dye indigo. The use of this plant of the crucifer family by ancient Britons to tint themselves blue has captured the popular imagination. Less well recognized is the fact that the cultivation of the plant and the production of the dye were principal features of Renaissance agriculture and commerce1. The woad industry declined because of competition from indigo produced from the tropical legume genus Indigofera and has disappeared with the advent of cheaper synthetic

indigo.

Indigofera plants contain colourless plant indican (indoxyl-β-D-glucoside), which on hydrolysis liberates indoxyl, which in turn oxidizes to the dye indigo. It is commonly supposed that the indigo of woad is also derived from the same indican and many modern references state this as fact²⁻⁵. Although the name indican was first coined in 1855 by Schunck⁶ to describe the indigo precursor in woad, it was, however, later used by him, and others for the indigo precursor of other plants, in particular those of Indigofera sp. and Polygonum tinctorium Ait. Its chemical nature in them was established⁸ as indoxyl-β-D-glucoside, to which the trivial name plant indican is now firmly

At the age of eighty, Schunck belatedly recognized that the properties of pure indoxyl-β-D-glucoside were incompatible with those of his woad substance, particularly with regard to the non-fermentable "peculiar sugar" the latter possessed. He proposed that the woad material be called α -indican, and indoxyl- β -D-glucoside be renamed β -indican. but this terminology has never been used.

The most convincing differentiation of the two indigo precursors was presented by Beijerinck¹⁰ at the turn of the century. He clearly demonstrated that woad indigo cannot come from indoxyl-β-D-glucoside. Briefly, the most compelling items in Beijerinck's argument were the facts that enzyme-free woad extracts reliably produce indigo only when treated with weak alkalis, while indoxylβ-D-glucoside is stable even to strong bases. Furthermore, plant and bacterial enzymes which hydrolyse indoxyl-ß-D-glucoside fail to act on woad preparations. Woad tissues contain an enzyme which Beijerinck named "isatase". Isatase action leads to the formation of indigo when it is incubated with woad extracts, but the enzyme fails to attack indoxyl-β-D-glucoside. Accordingly, Beijerinck concluded that a β -D-glucosidic indigo precursor could not be present in woad, but some other substance which liberates indoxyl for which he proposed the name "isatan". Perkin¹¹ confirmed the principal conclusions of Beijerinck's work, but his announced intention to isolate the woad colouring principle himself does not appear to have been

Unfortunately, Beijerinck's choice of the name isatan further confused the already far from clear nomenclatural situation. Isatane already had been employed in 1842 by Laurent12 to designate quite another substance for which a structure was not proposed until 1916 by Lefèvre¹³.

 $\mbox{\ensuremath{^{\circ}}}$ Present address: A.E.C. Plant Division Laboratory, Michigan State University, East Lansing.

Hansen¹⁴ confirmed by synthesis 8 yr later Lefèvre's suggestion that Laurent's isatane was 3-hydroxyl-3,3'bioxindole. It has been suggested that this substance, too, may not be assigned the correct name15 or correct discoverer18

None of these workers seem to have been aware of all of the terminology in use, and thus ambiguity still persists in reference works. For example, *Chemical* For example, Chemical Abstracts uses isatan to refer to Laurent's substance, while the isatan in the Merck Index is Beijerinck's compound. Laurent's name clearly has priority in time, but in view of their long co-existence, we suggest Beijerinck's name for the indigo precursor in woad be slightly amended to "isatan B" to avoid introducing entirely new terminology.

This situation was uncovered during the preparation of a review on plant indoles17, and has taken on new urgency with the reports that other indoles isolated from crucifers may be artefacts. For instance, both the plant hormonally active indole-3-acetonitrile and ascorbigen, which is of concern to animal nutrition, now seem to arise by enzyme action during isolation and are not natural products^{18,19}. Thus, study of another crucifer which produces relatively large quantities of an apparently indolic substance may east light on these other problems. Moreover, being employed by a university which bears the Celtic name of an indigo-trader who was its first benefactor²⁰, and whose principal educational efforts are devoted to the production of old Blues, a study of the origin of one of them seemed singularly appropriate.

Woad was grown in Yale University's Marsh Botanic Garden from seed either collected in the herb garden of Sissinghurst Castle, Kent, or purchased from Thomson and Morgan (Ipswich) Ltd. Fresh leaves were placed in boiling water, and the cooled solution extracted with ethyl acetate. The extract was evaporated to a small volume, and samples applied to thin-layer chromatographic plates coated with silica gel G and carboxymethyl cellulose21. Hexane: 2-butanone (1:1) was the most useful of several solvents22. Its resolution was improved by saturation with 0.5 molar formic acid. conditions a blue spot with the visible absorption spectrum of indigo developed at R_F 0.5 on spraying with 1 per cent sodium bicarbonate or with other mild alkalis, in agreement with the reported base lability of isatan B. Indole chromogenic sprays like the Salkowski and Ehrlich reagents²³ gave a blue and a fading purple reaction respectively at this locus. On the other hand, indoxyl-β-D-glucoside had an R_F of 0·1 in this system and did not react to bicarbonate. Indoxyl acetate and indoxyl sulphate (urinary indican) also were well separated from isatan B. Beijerinck's belief that a new substance is present in woad was thus readily confirmed by modern methods.

Accordingly, large scale isolation of isatan B was attempted. Quantitative estimations of the amount of isatan B obtained by different extraction media were made and these supported Beijerinck's report that mildly acid aqueous media are optimal and critical. We found boiling 0.2 molar formic acid: sodium formate buffer, pH 3.5, gave maximal yields of isatan B; appreciable losses

Fig. 1. Structure of isotan B, the woad from Isatis tinctoria L.

occurred at pH 2 or 5. Further studies showed ethyl acetate to be the most convenient solvent and partitioning the water extract five times with an equal volume of ethyl acetate transferred nearly all isatan B to the organic phase. The combined extracts were then evaporated to a smaller volume, dried over anhydrous sodium sulphate and evaporated to dryness. The brown powder so obtained was placed on a 100–200 mesh acid washed silica gel column and eluted with a gradient obtained from a 'Varigrad' with 50 ml. of chloroform in the first chamber and 200 ml. of ethyl acetate in the next two chambers. On a 19 mm diameter column containing 8 g silica gel, isatan B was found to elute after 130 ml. had been collected.

In large scale isolations, isatan B was accompanied by a red pigment, even after a second column chromatography on silica gel G or treatment with charcoal. Evaporation to dryness resulted in it darkening to a deep purple, very hygroscopic material. Repeated attempts to crystallize isatan B have failed, probably because of this contamination. Rapid smaller scale isolations from lyophilized leaves gave less than a milligram of material, but it was only slightly coloured and quantitative assays of both indigo production and sugar content indicated a purity of 60–70 per cent if the structure is as indicated in Fig. 1.

An ultraviolet absorption spectrum of isatan B suggested the presence of an indoxyl moiety and this was confirmed by a positive fluorindal reaction which is a specific test for indoxyls²³. Because the base lability of isatan B suggested it was an indoxyl ester, and its solubility properties indicated the likelihood that a sugar moiety was present, comparisons of the water soluble alkaline hydrolysis products were made after removal of the indigo by extraction with chloroform. Paper chromatography in various solvents indicated that a substance giving typical carbohydrate reactions, reducing 2,6dichlorophenolindophenol, and giving a yellow reaction to bromeresol green was present. It was easily separable from any of the common glyconic and glycuronic acids. No other carbohydrate was detected. Its reactivity to colour reagents seemed most compatible with 5-ketogluconic acid, a carbohydrate not previously reported in higher organisms, although it is known in bacteria. The calcium salt of this sugar was synthesized from glucose by the method of Barch²⁴. The chromatographic and colour reacting properties of the synthetic 5-ketogluconic acid were identical to the sugar acid in the isatan B hydrolysate, and could be distinguished from the otherwise very similar 2-ketogluconic acid (Table 1).

The calcium salt of the sugar isolated from the isatan B hydrolysate was crystallized from water at $p{\rm H}$ 5·0. It was first necessary to treat the hydrolysate with charcoal to remove a yellow pigment and then with 'Amberlite IR-120' to remove potassium ions. Then calcium hydroxide was added to bring the $p{\rm H}$ to 5·0, the volume reduced to 2 ml. by a flash evaporator and the solution kept in a refrigerator overnight. The salts of both the synthetic and the isolated acids lost water at 130° C but did not have a sharp melting point²4.

Final confirmation was the preparation of the semicarbazide derivative of both the plant and the synthetic sugar acids. The decomposition point of both was between 215° C and 220° C as expected²⁸.

Quantitative estimates of the keto-acid content of isatan B hydrolysate by the methyl-1-phenylhydrazine sulphate method³⁰ not only showed the characteristic spectrum of 5-ketogluconic acid, but on a molar basis were exactly twice that of indigo determinations indicating that one molecule of the acid is produced for each molecule of indoxyl. Isatan B is therefore indoxyl-5-ketogluconate. Because isatan B does not react to ketone reagents, the sugar moiety must be in the hemiacetal form. As only the furances structure is possible, the structure of isatan B can be completely specified as indicated in Fig. 1.

This identification has several points of general interest. First, it explains why assays of indican content of woad have been so low as to lead to doubts that it could have been an important Renaissance source of indigo. Analytical methods for indican which employ acid hydrolysis lead to considerable losses when applied to isatan B. Thus the results reported by Berkeley³¹ probably must be multiplied by three or four times to obtain correct indigo contents of woad leaves, and this reduces his calculations of the masses of plant material which must have been handled by the woad industry to a more reasonable value. It is probably still the case, however, that one of the principal values of woad was not as the primary dye source alone, but as a favourable medium for the bacterial fermentation which reduced indigo to leuco indigo, a necessary step in the dyeing process.

Second, the presence of relatively large quantities of a 5-ketogluconic acid derivative in a higher plant has relevance to the still unsettled question of the pathway of ascorbic acid biosynthesis. Indeed, on largely theoretical grounds Loewus and co-workers³² have proposed a 5-keto sugar acid intermediate; their suggestion has been critically discussed by Isherwood and Mapson³². Because woad, like other crucifers, has a high content of ascorbic acid³⁴, it should be good material with which to test the relationship. In this connexion, it also is noteworthy that 5-ketogluconic acid readily reduces 2,6-dichlorophenolindophenol in conditions that are usually considered specific for ascorbic acid. It may be, then, that estimates of ascorbic acid for dietary and other purposes, which have not included a chromatographic separation, have been erroneous, particularly when applied to the many edible crucifers.

Third, ascorbic acid also brings to mind the substance ascorbigen, once thought to be a natural product in many crucifers and to be of dietary importance to animals, but which is now believed to be an artefact produced by condensation of ascorbic acid with decomposition products of glucobrassicin18,19. Ascorbigen is found in woad extracts too, but the connexion with glucobrassicin has not yet been studied. The structure of ascorbigen is still uncertain, but its structure obviously has similarities to that we are proposing for isatan B. Isatan B itself is not likely to be an artefact, for we have rapidly extracted it both from fresh and from quick frozen lyophilized woad leaves with several solvents, and the highest yields are obtained when the solvents are boiling and should be inactivating enzymes. It is believed ascorbigen can be synthesized non-enzymatically from indole, formaldehyde, and ascorbic acid, as well as from the myrosinase induced hydrolytic products of glucobrassicin plus ascorbic acid18. But because ascorbigen, like isatan B, has not been conclusively purified and has an indefinite melting point, the

homogeneity and identity of these condensation products are open to question. Our results suggest that the structure and potential natural role of ascorbigen deserve further examination.

Finally, because many indigo producing plants are known from widespread parts of the plant kingdom, it is possible that isatan B is not the only exception to the previously accepted generality that indican is the sole precursor of indigo. Hadders³⁵ himself notes, in his comprehensive listing of indigo producing species from twentythree genera of nine families, that it is the formation of indigo, not the presence of indican, which has been reported in all but a few instances. Some of these plants accumulate several per cent dry weight of the indigo precursor, and thus seem to be the materials of choice for investigations of indole biogenesis in higher plants, rather than those plants forming much smaller amounts of indole alkaloids which have until now received the most biochemical attention.

We thank Dr Ž. Procházka for helpful discussions, Mr D. C. Turner who performed preliminary studies, and Miss Martha Sokolowicz and Mr L. Hirni for assistance with the literature. Nongenetic Transmission of Information

VICTOR H. DENENBERG KENNETH M. ROSENBERG

Department of Psychology, Purdue University, Lafayette, Indiana

The handling of female rats in infancy has been shown to affect the activity and weaning weight of their grandchildren.

WE have shown that one significant determinant of the rat's behaviour is the handling experience of the mother while she was an infant¹. This experience was profound enough to modify her offspring's weaning weight and open field performance in adulthood. Thus the experience of one generation was visited on the next generation. Such a finding would appear to have broad implications for the evolution of behaviour. In this context a relevant question is: How far into the future can such effects extend? We have investigated this question by determining whether the experiences of female rats during their infancy would significantly affect the behaviour of their grandpups.

Again within an evolutionary framework, the habitat in which the animal is born and reared is known to affect profoundly his subsequent performance. We have shown that rats which are born and reared in a complex free environment between birth and weaning, or which are given free environment experience after weaning, differ along a number of behavioural dimensions from rats which are reared in standard cages during infancy and after weaning²⁻⁵. Thus for the laboratory rat, cages and free environments may be thought of as two different habitats. We investigated the effects of these habitats on the offspring's behaviour in this experiment.

The grandmothers' experience was as follows. birth, litters of Purdue-Wistar rats were reduced to eight

pups. Whole litters were randomly assigned to groups to be handled or not handled. Handling consisted of removing the pups from the maternity cage, leaving the mother in the cage, and placing each one into a tin can partially filled with shavings. The pups remained in the cans for 3 min and were then returned to their home cage. This procedure was followed once a day from day I until day 20. Non-handled controls were not disturbed between day 1 and 21, when all litters were weaned. The handled and non-handled females from these litters were the grandmothers of the animals used in this study. They were bred when about 100 days old. When pregnant, the females were assigned randomly to one of two housing conditions, to be described later.

The mothers' experiences were as follows. The females were placed either into stainless steel maternity cages (15 in. \times 10 in. \times 7.5 in.) or into free environment boxes. These boxes were triangular compartments formed by placing a diagonal insert into a 34 in.2 box. Food was scattered on the floor, water was supplied by an externally mounted bottle, and "toys" (wooden block, can, ramp, running disk) were placed into each environment. At birth, litters were cut back to eight subjects consisting of four to six females.

When weaned on day 21, the females from each litter were randomly split into two groups, one going into a stainless steel laboratory cage (11 in. $\times 8.25$ in. $\times 7.5$ in.),

Table 1. SUMMARY OF MEANS FOR ALL EXPERIMENTAL CONDITIONS

and the other into a free environment. The free environments were the same as previously described except that the diagonal partition was removed. Two or three females were placed in each laboratory cage, while ten to twelve pups shared each free environment. On day 50 the females from the free environment were placed in the same type of laboratory cages as those described above.

These females were the parents of the animals used in this study. When approximately 150 days old, one female from each litter was bred to a randomly chosen colony male. All pregnant animals were placed in stainless steel maternity cages. At birth, litters were reduced to eight pups consisting, when possible, of four males and four females. No litter contained less than four pups. The pups remained undisturbed until they were 21 days old. At this time they were placed into a 32 in.2 open field consisting of sixty-four squares. An activity count was recorded each time a pup made contact with a different square. Each pup was given one 3 min test, and after this was weighed.

Table 1 presents the experimental design, the mean activity score, the mean body weight, the number of pups and the number of litters for each of the eight treatment combinations. In the statistical analysis of these data the litter was used as the unit of measurement with a sub-classification for the sex of the pup. For example, the activity scores of all males within a litter were combined and a mean was obtained; the same procedure was applied to the females. These litter sex scores were subjected to a split plot unweighted means analysis of variance. All F tests were based on 1/47 degrees of freedom.

Activity

The interaction of grandmother handling \times mother preweaning housing was significant at the 0.01 level (F, 7.68): descendants of non-handled grandmothers were more active than descendants of handled grandmothers if their mothers had been reared in a maternity cage between birth and weaning. Exactly the opposite pattern was obtained if their mothers had been reared in a free environment during infancy. The grandmother handling × mother postweaning housing interaction was significant (F, 5.04; $\hat{P} < 0.05$): the pattern was just the opposite to that described for the previous interaction. In addition, the preweating housing \times postweating housing interaction was significant at the 0.05 level (F, 5.77). Offspring of mothers reared in two different environments during early life (that is, cage and free environment, or free environment and cage) were more active than the offspring of mothers which had been reared only in cages or only in free environments for the first 50 days of life.

The grandmother handling \times sex interaction was significant at the 0.01 level (F, 21.44). Male weanlings were only slightly affected by the handling experience their grandmothers had received, while the females were markedly affected, with grandpups of handled females being significantly more active than grandpups of non-handled females. Finally, the preweating housing x postweating x sex interaction was significant at the 0.05 level (F, 4.55).

Weaning Weight

The two main effects of grandmother handling and mother postweaning housing were both significant at the 0.05 level (Fs of 4.55 and 5.20, respectively), while the interaction of these two factors was significant at the 0.01 level (F, 8.49). All three of these effects were brought about by one cell: those weanlings whose grandmothers were not handled in infancy and whose mothers were reared in laboratory cages after weaning weighed significantly more than the other three groups making up this interaction. Such groups did not differ among themselves. In addition, the grandmother handling x preweaning housing x postweaning housing interaction was significant (F, 18.80; P < 0.01), and sex was significant $(\overline{F}, 87.99;$ P < 0.01) with male weanlings weighing more than females.

These data for activity and weaning weight reveal that handling females in infancy can have an effect two generations further on; that the nature of the mother's living quarters during her early life will affect her offspring, and that these variables act in a non-additive interactive manner. The interactive nature of the variables should be emphasized: if we had merely taken the female offspring of handled and non-handled grandmothers and maintained them in standard laboratory caging conditions from birth until adulthood (first and fifth groups listed in Table 1) most of the significant findings would have disappeared. Thus the occurrence of free environment experience some time during the mother's early ontogeny was necessary for the effects of the grandmother's handling experience to express itself in the grandpups.

Others have reported findings extending into the next generation. Ginsburg and Hovda⁷ reduced the incidence of death from audiogenic seizures in dba mice by transplanting fertilized dba eggs into C57Bl foster mothers shortly after fertilization, and Ressler⁸ has shown that the strain of foster grandparent rearing young mice will influence the operant response rate of the offspring of those mice. As far as we know, the present experiment is the first documentation that the experiences which an animal has in early life will influence her unborn descendants two generations away by nongenetic mechanisms.

The nature of the mechanisms underlying these effects is not known. Both handling and free environment experience has behavioural and biological effects on the stimulated organisms2-5,8-12. These effects could act through changes in grandmaternal or maternal behaviour or through physiological changes which would affect the developing foetus or modify the milk supply of the grandmother or mother.

Amide Cotton Effects of Heparin

AUDREY L. STONE

Laboratory of Neurochemistry, National Institute of Mental Health, Bethesda, Maryland Heparin displays the ultraviolet Cotton effects common to amide substituted polysaccharides. These effects are useful for investigating the conformational alterations, which heparin undergoes with changes in pH, or the addition of biogenic amines.

The relationship between macromolecular conformation and biological functions in polysaccharides is largely unknown because the techniques which have been used for proteins and nucleic acids have had limited applicability or been unsuccessful. The recent finding that mucopolysaccharides as diverse as heparin and chondroitin sulphate have distinct and particular optical properties possibly related to the preferred order of their amino-sugars provides a new means of examining the conformations of these biopolymers in solution.

Heparin, a highly anionic mucopolysaccharide, is involved in two basically different types of biological phenomena: (a) receptor function for histamine and serotonin, for example, in the mast cell; and (b) inhibition of blood clotting proteins and stimulation of lipid clearance in the circulation probably based on non-polar as well as polar interactions with proteins. We have demonstrated by an optical method that heparin has several conformational forms, and this helps to separate the different parameters of its multiple biological roles. All mucopolysaccharides examined so far show amide Cotton effects. These results will be reported separately.

Optical rotation was measured in the Cary model 60 spectropolarimeter and absorption was measured in the Cary model 15 spectrophotometer. Heparin samples were described earlier²⁻⁵.

Fig. 1a shows the ultraviolet Cotton effect in the range $185-220~\mathrm{m}\mu$ for a given solution of H-IV at pH 7 and $2\cdot6$. Although there is a greater noise level for the acidic solution because of the increased absorbance of the solvent, both an increase in the magnitude and a hypsochromic shift in the wavelength of the peak of the Cotton effect were reproducibly obtained. The optical rotatory dispersion (ORD) of H-II ($2\cdot85~\mathrm{mg/ml.}$) at pH 7 and $2\cdot6$ shows the same pattern and change as that illustrated for H-IV. Fig. 1a also shows the changes in the absorption of heparin in the same spectral region. In these conditions, the absorption band of the amide transition is not resolved, but hypochromism accompanies the rotational changes when the pH becomes acid.

Systematic slight changes in rotation appeared to occur at about 230–220 m μ at different pHs using the 0.5 mm path, and so the ORD between 280–220 m μ was investigated at 5 and 10 mm path. The results in Fig. 1b show that the original ORD curve¹ from 250–190 m μ at neutral pH contained an unresolved, smaller Cotton effect. Furthermore, the absorption in this region is slightly hyperchromic. Preliminary measurement of the circular dichroism of neutral heparin showed a small negative band preceding the much larger positive band in that spectral range (that is, 250–190 m μ). Thus it seems that a first, negative Cotton effect is enhanced in the acid form. The difference curve shown in Fig. 1b shows that the trough of this Cotton effect is ~232 m μ . The family of curves intersects at ~217 m μ .

The relation of pH to the changes in optical properties was readily determined for the first Cotton effect (Fig. 1b), but a regularly varying family of curves from 220–185 m μ could not be obtained for pHs 7–2·4 because of the de-

creasing signal to noise ratios and baseline variations of the acidic solutions, especially because the serial changes in pH could not be made with the same solution in the cell. There may be variation among the separately prepared solutions. Table I presents the values of the molar rotation Φ at the various wavelengths for a number of solutions at neutral pH at different concentrations of H-IV using three different Cary model 60 instruments during its development, with successively better penetration in the ultraviolet spectral range 195-185 mμ. The average Φ value for each wavelength was made for the concentrations from 1-2.68 mg/ml. showing that peak values (200 mµ) range from $75-90 \times 10^2$ with an average value of 8,100. In general, the shapes of the neutral curves are similar (see ratios Φ_{190}/Φ_{200} and Φ_{195}/Φ_{200}). Increased relative optical density of the solvent (that is for runs at 1 mm compared with 0.52 mg/ml.) seems to cause experimental errors towards higher values at 190 mµ. Increasing the ionic strength of the solvent from no added electrolyte to 0.005 molar sodium chloride (Table 1) or raising the pH to 8.0 did not affect the ORD of H-IV at a concentration of 1.01 mg/ml.

Table 1 shows the Φ values and experimental variation at pH 2·4-2·7. The $\Phi_{190/200}$ ratio in acid becomes about 2.5 times greater at neutral pH and the peak is displaced ~ 5 mm. Inspection of the data shows a bimodal peak (~ 200 mm and ~ 195 mm) which may be the result of experimental error. The data at intermediate pHs show the same irregularities in several cases. Points were averaged to yield a smooth acid curve for Fig. 1a. The data for the intermediary pHs were also averaged within certain pH ranges to sort out changes caused by experimental variation from those caused by pH. In general, the shape of the curves shifted more regularly with pH than the individual values of the rotations at the peak. The same changes with pH were found for H-II (not shown) as were found for H-IV (Fig. 1b). The difference curve gives in addition a suggestion of a peak at 210 mu with maximum change at 190 mµ and a sharp fall towards

The strong binding of histamine to heparin in aqueous solution has been demonstrated previously^{7,8}. Fig. 1c shows the effect of histamine on the ORD of heparin in the range of the negative Cotton effect. It can be seen that the conformation of heparin in the histamine—heparin complex at $pH \sim 6.5$ differs from that of neutral heparin alone. Histamine binding enhances the negative Cotton effect to a greater extent than that found in heparin alone at pH 2.6, but the minimum is at 225 m μ . The degree of change depends on the histamine to heparin ratio as would be expected from binding studies⁷; however, the maximum change in the trough occurs at a ratio of less than one histamine to each sulphamino group under these conditions.

Serotonin also causes the appearance of the trough at 225 m μ ; however, decreased signal to noise ratio as a result of its absorbance precluded measurements below 225 m μ at ratios of serotonin to heparin sulphamino groups of 0·135 and more in these conditions. Table 1

shows the ORD in the range 185 to 220 m μ for the serotonin–heparin complex, ratio 0·125, showing the changes in the same direction as the acid form (that is, increased Φ and hypsochromic shift) but to a small extent.

The optical rotatory dispersion of heparin (and other mucopolysaccharides) contains at least two Cotton effects in the region of amide-transition bands. Previous work has shown that amino derivatives of simple sugars and polysaccharides containing these derivatives show negative Cotton effects near 200 mu while simple

polysaccharides show plain dispersion to 200 m μ . The amino derivative in heparin is sulphamino glucose

In the present study, the ORD of polygalacturonic acid was measured to assess the possible role of carboxyl groups in the ultraviolet Cotton effects because heparin

Cary model 60, full scale sensitivity 40 mdegrees, 30 sec/period. b, Changes with pH of H-IV ORD in the spectral range 280-220 m μ . Curves 1-7 are those at pH 7, 6-1. 5-5, 5-0, 4-4, 3-1 and 2-7, respectively, for a given heparin solution, 1-52 mg/ml., at a path length of 0.5 cm. The inset is the difference curve between curves 1 and 7. c, Curves 1 and 4 are the neutral (pH 7) and acid (pH 2-7) ORD for H-IV. Curves 2 and 3 are for the histamine-heparin complexes, ratio of biogenic amine to sulphamino group of 0-37 and 0-79 and pH 6-9 and 6-3, respectively, at a heparin concentration of 0-88 mg/ml. These concentrations of histamine caused either no change or a shift similar to low concentrations of sodium chloride in the water baseline. Changes in ORD are attributed to changes in conformation of the heparin chromophore rather than to dispersion interactions between histamine and heparin.

is composed of dimeric units of sulphamino glucose and glucuronic acid. Polygalacturonate in the spectral region 350-185 mu had a plain dispersion curve of increasing positive rotation which was the tail of a positive Cotton effect in the low ultraviolet major absorption band of the polysaccharide. Thus it seems that the first negative Cotton effect is probably caused mainly by the sulphamino group (trough about 230 mu). In the case of neutral heparin the trailing ends of the positive rotational bands in the low ultraviolet plus the positive Cotton effect for the 185 mu amide transition mask the relatively small negative Cotton effect. On acidification, a structural change occurs in heparin which causes the enhancement of the 230 mu trough. Furthermore, there is either a shift in the position of the π - π amide band or the appearance of a new peak at about 190 mu. Changes in ionization of the carboxyl group could affect the ORD of heparin around 215 mu, and so the negative circular dichroism band should be studied further to resolve the possible mixed Cotton effects in the 220-230 mu regions. changes in pH were limited to the pH range in which the carboxyl group ionizes, avoiding lower pHs where the sulphate groups (especially the labile sulphamino group) would also be affected. The data indicate that further change would occur below pH 2.7 (Fig. 1b) because there was a significant change from pH 3·1 to pH 2·7. The greatest change in the trough per unit change in pH occurs at about pH 5.0.

The optical properties of heparin and the heparinhistamine complex support the idea that specificity of conformation explains the relative strength of histamine binding by a given heparin preparation^{3,7} and that conformation changes in heparin may accompany the release of histamine which causes the anaphylactic shock concomitant with degranulation of the mast cell in vivo. The origin of the heparin amide Cotton effects lies in the degree of order involving the sulphamino groups. It has been proposed³ from a consideration of the all 1,4-α glucosidic chain with the possibility of helical twisting of charged groups¹⁰ that a preferred orientation could be stabilized by a hydrogen bond involving the sulphamino group and the C_3 hydroxyl of the following uronic acid. This conformation also provides a molecular groove which accommodates a histamine molecule, fitting in the distance between the sulphamino and carboxyl groups with additional possibility of stabilization by nonpolar attraction between the histamine ring and the two axial C-H groups. These data show that histamine binding stabilizes a given molecular order in heparin (seen also in

acid solution) which gives relative enhancement of the negative presumably $n-\pi$ amide Cotton effect. T effect of histamine on the conformation of heparity cand relates to the π - π amide band is still undetermined because of technical limitations; however, at low rates of histamine to heparin the ORD changes in the π π region are similar to that shown for serotonin (Table 1) Quantitative comparison of the effects of the bine ag f biogenic amines and their liberator substances mist in studied further in new conditions where ORD changes can be measured more accurately. For example, cosidering the relatively high concentrations of the historian liberator 48/80 required to antagonize heparin' it may not be surprising that at the low concentrations need sitated by these measurements 48/80 has no appara conformational effect on neutral heparin; on the other hand, it may act by preventing the formation of the heparin structure which favours histamine binding 1 general, it may be considered that secondary order in mucopolysaccharides is in a dynamic state readily in fluenced by other substances in the biological system in which they operate (another example might be the chondroitin sulphate-calcium deposition system in b no formation at the epiphyseal plates).

A conformational change in heparin from pH 2.4 6.1 was suggested previously3 from the changes in incurred (extrinsic) Cotton effects in heparin-methylene blue ecoplexes. At pH 6.7 the presence of histamine caused light changes in the extrinsic effect which were similar in kine to the changes in the induced Cotton effects in herein methylene on going to acid pHs (refs. 1-3). Extrinsic Cotton effects of this magnitude in bound dyes must depend on a net helical order of dye in a given "harded ness", and so the acid-form may have greater molecular order than the neutral form as a first approach to the interpretations concerning the origin of the negative Cotton effect centred about 2175 Å.

Nuclear Control of a Cytoplasmic Enzyme in Acetabularia

by H. G. SCHWEIGER R. W. P. MASTER* G. WERZ

Max-Planck-Institut für Meeresbiologie, Wilhelmshaven, Germany

In four different species of Dasycladaceae (Acetabularia) the isozyme pattern of malic dehydrogenase was found to be species specific. Interspecific nuclear transfers changed the isozyme patterns of the recipient species to that of the nuclear donor species.

THE giant unicellular alga Acetabularia is a good material for studies of activity of the nucleus and its regulatory influence on the cytoplasm. Hämmerling¹ has shown that: (a) the process of morphogenesis in certain species of Acetabularia is dependent on substances which are produced by the nucleus and which determine the speciesspecific morphology; (b) this process can take place in the absence of the nucleus for several weeks, indicating the stability of the morphogenetic substances; (c) the morphogenesis of one species of Acetabularia can be altered by the transplantation or implantation of a nucleus from another species. The morphological characteristics, particularly the stalk and cap formation, in the presence of a foreign nucleus are either completely or partially determined by the activity of the foreign nucleus, and resemble those of the nuclear donor species. In molecular terms these experiments prove that genetic information originating in the nucleus can be stored in a stable form in the cytoplasm.

Using the isozymes of malic dehydrogenase (MDH) as a molecular marker for the four species of the family Dasycladaceae—Acetabularia mediterranea (med), Acetabularia crenulata (cren), Acicularia schenckii (acic) and Polyphysa (Acetabularia) cliftonii (clift)—we have studied the effect of a foreign nucleus on the cytoplasm of these four species. Experiments on the influence of transplanted nuclei on the isozyme patterns of esterase2 and phosphatase³ reported previously failed to give clear evidence

of any nuclear effect.

The four species were grown under normal conditions4. Cells just prior to cap formation were used for grafting experiments. The preparation of enucleate (apical) and nucleate (basal) parts and the technique of transplantation were described by Hämmerling¹. The grafts were allowed to recover overnight in the culture medium in dim light and then observed for 28 days in normal light conditions. In other experiments, the nucleus from a donor cell of one species was isolated and implanted into the cytoplasm of a host of a different species and observed for 28 days.

After 28 days the cytoplasm was analysed for MDH isozymes by acrylamide gel disc electrophoresis. In each case, the nucleus of the cell was removed by amputating the rhizoid with stainless steel scissors and the entire cytoplasmic contents were then squeezed out and transferred into 0.4 ml. of the large pore acrylamide solution. 0.1 ml. of this solution was photopolymerized for 35 min4. We used the buffer system described by Davis⁴ at 1/5 the concentration for the electrophoresis. A current of 4.5 m.amp (300 V) was applied to each tube (6 mm × 75 mm) at 18° C for 35 min. After electrophoresis, the gels were incubated for 90 min in the dark at 18° C in 5.0 ml. of a medium made by mixing 3 ml. of sodium-p,r-malate (0.25 molar), 0.2 ml. of NAD (30 mg/ml.), 0.4 ml. of phenazine methosulphate (5 mg/ml.), 0.4 ml. of nitro BT (10 mg/ml.) (Serva) and 16 ml. of tris-HCl buffer

* Stipendiat der Alexander von Humboldt-Stiftung.

(0.05 molar), pH 8.4. After incubation the gels were washed with deionized water and stored at 4° C.

MDH activity was determined by the method of Ochoa⁵. Single cells were homogenized in 0.5 ml. of 0.25 molar tris buffer, pH 8·7, containing 50 μl. 'Triton X-100'/ml. One ml. of the test solution contained 212 mumoles NADH, 380 mµmoles of oxaloacetic acid, 100 µmoles tris-HCl at a pH of 8.7 and the enzyme. Enzyme activity was expressed as mumoles/min at 20° C. Non-enzymatic degradation of oxaloacetate to pyruvate did not interfere with the NADH oxidation because lactate dehydrogenase activity is considerably smaller than MDH in Acetabularia (unpublished results). MDH was also demonstrated histochemically in the cytoplasm of all four species using the nitro BT stain techniques.

Malic dehydrogenase isozymes in Acetabularia. preliminary investigation, the four species of Dasycladaceae were examined for differences in their specific isozyme patterns. A. mediterranea, A. crenulata, Acicularia schenckii and Polyphysa cliftonii had highly species-specific MDH isozyme patterns characterized both by the number and the positions of the bands

(Fig. 1).

These species-specific differences between the MDH isozyme patterns were confirmed by mixing the cytoplasms of the different species and then subjecting them to electrophoresis (Fig. 1). The two isozyme bands of A. mediterranea were not distinguishable from the first two of the five bands of A. crenulata. The sole isozyme band of *P. cliftonii* is distinct from the three bands of *A. schenckii*. Thus although there is no marker for *A*. mediterranea, the prominent third and fifth bands of A. crenulata, the third band of A. schenckii and the solitary band of P. cliftonii are good markers for these three species.

MDH isozyme patterns after enucleation. Acetabularia is known to form a species-specific cap and stalk even after enucleation. This indicates the morphogenetic capability of the cell even in the absence of the nucleus. Thus it was of considerable importance to see whether the species-specific MDH isozyme pattern was affected by enucleation. Cells of each of the three species, med, cren and acic, were enucleated by amputation of the rhizoids and samples were examined for the MDH isozyme patterns at different intervals up to 28 days. The MDH isozyme pattern was found to be essentially identical with that of the nucleated cells in all three species even 28 days after enucleation. In the 4 weeks following enucleation the total activity of MDH substantially increases (Table 1). This increase is, however, less pronounced than in nucleate cells. An increase in enzyme activity in enucleate cells has been reported previously1.

After enucleation the positions and relative concentrations of the different isozyme bands remain constant. It follows that in the enucleate cells the activities of all isozymes increase to more or less the same extent.

Table 1. TOTAL ACTIVITY OF MDH IN NUCLEATE AND ENUCLEATE CELLS

Day	Nucleate	Enucleate	
0	17·4	17·4	
28	52·2	33·3	

The nuclei of the nucleate cells were removed just before homogenization and enzyme determination. Enzyme activity in m μ moles/min/cell at 20° C.

Furthermore, because enucleation does not affect the isozyme pattern, any changes in this pattern produced by transplantation or implantation can be attributed to the influence of the foreign nucleus.

Transplantation. Transplantation experiments, in which the rhizoid of one species was grafted to the stalk of another, were performed for all possible combinations among med, cren and acic and between med and clift. In each case 4 weeks after the transplantation the cytoplasm was subjected to gel electrophoresis and the gels were stained for MDH activity.

In some of the combinations between med and cren (med₁ cren₀ and cren₁ med₀; Fig. 2), the MDH isozyme pattern was changed to that of the nucleus donor species. These experiments demonstrate that, under the influence of the heterologous nucleus, some sort of transformation takes place. In some experiments, however, the transformation was either incomplete or failed to occur. We refer to such results as "unsuccessful". The percentages of successful and unsuccessful transplantations depended on the particular combination. In all cases, successful transformation was accompanied by definite morphogenetic effects. In the case of cren, med, combinations, all ten experiments were successful with the appearance of cren-specific MDH isozymes in the cytoplasm of med. But in the med, eren, experiments only six out of a total of fifteen were successful transformations. A successful combination of this type only means that the third and fifth cren isozymes disappeared. The appearance of the fourth isozyme band in cren is too variable to be used as a marker. Nothing can be said about the appearance of the med isozymes, for they cannot be distinguished from the corresponding eren isozymes. In the unsuccessful transplants of the med, crene type the pattern was intermediate between cren and med and in some cases the

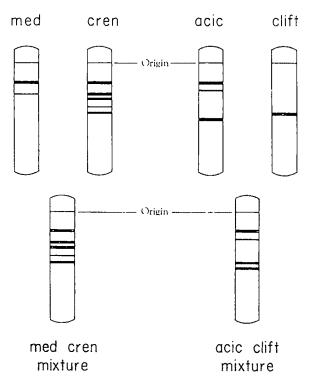

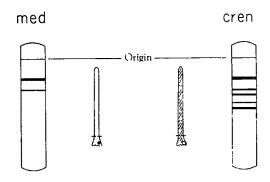

Fig. 1. Isozymes of MDH in Acetabularia and the effect of mixing cytoplasms.

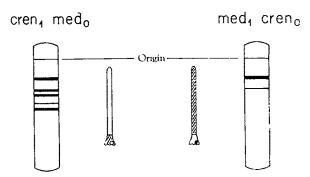

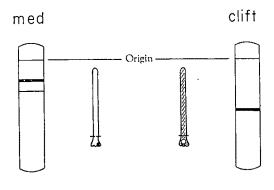

Fig. 2. Transplantation experiments between med and cren; , denotes the presence and denotes the absence of the nucleus of that species.

pattern was more like that of cren than that of med. Intermediate MDH isozyme transformation was accompanied by intermediate morphological changes. Such intermediate morphogenesis of transplants has been described in detail by Werz⁷.

Another series of experiments included combinations of med or cren with acic. All twelve experiments with combinations of the med, acic, type were successful; the second acic-specific MDH isozyme band disappeared with a simultaneous appearance of the faster moving med MDH isozyme (Fig. 1). The typical fast moving acic MDH isozyme band either disappeared or was reduced to a very faint band. In the reverse grafts acic, med, the second med band was considerably diminished but still appeared in most of the grafts, and a faint band corresponding to that of acic was observed after 28 days. In all ten experiments with cren, acic, combinations, the MDH bands specific for crenulata appeared and the acic isozymes disappeared or decreased simultaneously. In the corresponding acic, cren, combinations the isozyme pattern was intermediate between those of acic and cren. The fifth band of cren was considerably diminished with a simultaneous appearance of the fast moving acic MDH isozyme, but the second and the third intense MDH isozyme bands of eren still persisted almost undiminished even after 28 days.

Implantation. To exclude the possibility that the changes of the isozyme patterns after transplanting a heterologous rhizoid are caused by the accompanying cytoplasm, we performed implantation experiments in which an isolated heterologous nucleus was implanted. The eight eren, med, implantations produced the same results as the transplantation experiments and the expected pattern of the eren MDH isozymes was obtained in all the cases. In three out of four med, eren, implantations the eren specific isozymes were considerably diminished and the fourth revealed an MDH isozyme pattern identical to that of med. Results similar to those of corresponding transplantation experiments were also obtained in eight acic, med, and one acic, eren, implantations. The appearance of the fast moving acic MDH isozyme was especially prominent.

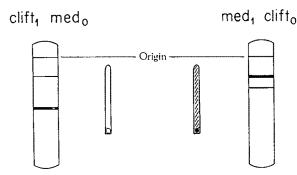

Fig. 3. Implantation experiments between med and clift; , denotes the presence and $_0$ denotes the absence of the nucleus of that species.

P. cliftonii has one very prominent MDH enzyme moving faster than the faster band of med and can easily be distinguished in a mixture of med and clift cytoplasms. Four weeks after nuclear implantations of the clift, med, type, the second med isozyme completely disappeared in five out of ten experiments and the first prominent band was reduced to a very faint band (Fig. 3). The prominent clift band appeared in all cases. The remaining four experiments revealed an intermediate behaviour of different degrees. In the reverse combination of med, clift, the clift band completely disappeared and the two med MDH isozymes appeared in four cases out of eight. In the remaining four cases the MDH pattern was intermediate between med and clift and corresponded quite well with the morphogenetic success of the implant.

Localization of MDH activity. In three species—A. mediterranea, A. crenulata and Acicularia schenckii—MDH activity could be demonstrated in the chloroplasts with a nitro BT stain technique using the same constituents as those for the disc electrophoresis except that the buffer medium was Erdschreiber medium.

An attempt was made to demonstrate MDH activity in isolated cell fractions. In both A. mediterranea and A. crenulata almost all the activity was localized in the particulate fraction sedimenting at about 500g. Quantitative determination of MDH activity using the oxaloacetate-NADH system⁵ showed that in A. mediterranea, A. crenulata and A. schenckii 95 per cent of the activity was in this particulate fraction and only 5 per cent in the supernatant. For further localization, a "cytoplasm fraction" was prepared from A. mediterranea by a method based on that of Thalacker and Behrens*. A crude chloroplast preparation obtained from this "cytoplasm fraction" was subjected to density gradient centrifugation in a carbon tetrachloride-petrol ether system. This method prevents losses of activity by excluding water from the system. Fractionation, after centrifugation, and estimation of chlorophylls and MDH activity revealed that the amounts of chlorophylls and the enzyme activity parallel each other. This provides further evidence that enzyme activity is associated with the chloroplasts (Fig. 4). By subjecting the pooled fractions containing chlorophylls

to disc electrophoresis the two typical med MDH isozymes could be demonstrated. Our results are interesting for several reasons. We have proved at the molecular level that the four species studied differ in their MDH isozyme patterns. The persistence of the MDH isozyme pattern and the increase in MDH activity even 28 days after enucleation again mean either that the isozymes are stable over weeks or, more probably, that synthesis of specific protein takes place in Acetabularia even in the absence of a nucleus¹, in which case the synthesis of all the isozymes of MDH should be under the direction of stable cytoplasmic messenger RNA. This result resembles the observations of Hämmerling¹ on the morphogenesis in Acetabularia in the absence of a nucleus.

The presence of a foreign nucleus in the enucleate cytoplasm results in the appearance of the specific MDH isozymes under the influence of the heterologous nucleus (Figs. 2 and 3) and in the disappearance or decrease of certain previously existing MDH isozymes. It follows that the heterologous nucleus causes the appearance of certain molecular characteristics. Furthermore, our results demonstrate that there is a close relationship between cytoplasmic transformation at the molecular This follows level and morphogenetic transformation. from the fact that in both transplants and implants a full morphogenetic response is accompanied by the complete transformation of the isozyme pattern. An incomplete morphogenetic effect was accompanied by an intermediate isozyme pattern.

It is noteworthy that in the cytoplasm the homologous MDH isozymes disappear under the influence of a heterologous nucleus while the same isozymes not only persist but even increase in amount 28 days after enucleation. This suggests that in the absence of the nucleus the synthesis of the MDH isozymes is directed by the stable messenger RNA in the cytoplasm and that under the influence of a heterologous nucleus these isozymes are eliminated from the cytoplasm by a special regulatory mechanism which is not yet known. It might well be that this type of regulation operates at the translation level. It remains an open question how, if at all, a homologous nucleus influences the isozyme pattern of the MDH in the cytoplasm.

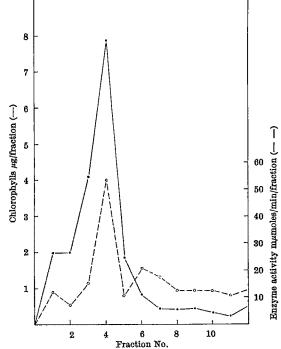

Fig. 4. Density gradient centrifugation in the carbon tetrachloridepetrol ether system of a chloroplast preparation.

The nuclear dependence of the MDH isozymes in Acetabularia raises the question of their subcellular We have shown biochemically and histochemically that these enzymes are associated with the chloroplasts. Because all the isozymes of the different species under investigation are nuclear dependent it is highly probable that there are enzymes in the chloroplasts of Acetabularia which are controlled by the nucleus. The nuclear dependence of a chloroplast enzyme is not surprising if the amount of DNA per chloroplast in Acetabularia is not sufficient to code for all the proteins in these organelles¹⁰. Chloroplast MDH may be synthesized in the cytoplasm and transferred to the chloroplasts, or, alternatively, the messenger RNA directing the synthesis of MDH may be transferred from the cytoplasm into the chloroplasts. Chloroplasts, and probably mitochondria, are not only able to survive and to carry out functions in the absence of the nucleus¹¹ but also multiply¹². means that there is some sort of autonomy. On the other hand, the nucleus is known to direct autonomous functions like RNA synthesis in chloroplasts^{11,13}. The mechanism of nuclear dependency of chloroplast enzymes shown in this article for the MDH might explain the nuclear effect on otherwise autonomous functions.

We thank Mr H. Kretschmer for his assistance in the transplantation and implantation experiments.

Effects of the Food Additive Butylated Hydroxytoluene on Monolayer Cultures of Primate Cells

by SUSAN M. MILNER Department of Pathology, University of Cambridge

Inhibition of monkey kidney cell numbers by the antioxidant food additive, butylated hydroxytoluene, is caused by a rapid depression of cellular metabolism. This effect varies according to sex and may be the result of more rapid metabolism of butylated hydroxytoluene

AUTOXIDATION of unsaturated fatty acids involves the formation of free radicals during the induction period leading to the breakdown of carbon-carbon double bonds and consequent rancidity. Butylated hydroxytoluene (BHT), or 3,5-ditertbutyl-4-hydroxytoluene, acts as an antioxidant by accepting free radicals1. The onset of rancidity in foods containing lipids may therefore be delayed by the addition of BHT. The safety of BHT as a food additive remains suspect. It is not included on the list of permitted antioxidants in many countries2, despite pathological, teratogenic^{3,4} and biochemical tests⁵⁻⁸ which indicate that BHT is a harmless compound in low doses.

Rats are the animals most frequently used for in vivo studies of BHT, and the oral dose required to cause an increase in relative liver weight and in the concentrations of drug metabolizing enzymes and urinary ascorbic acid is about 500 mg/kg body weight. It has, however, long been recognized that experimental animals other than rodents are required for toxicity studies of compounds for human consumption9 because of species differences in the type and rate of metabolism10,11.

In view of the questionable status of BHT as a food antioxidant, the in vivo results, and a possibility of species specific metabolic differences, it was considered important to examine the effects of BHT on primate cells. Primary cultures of monkey kidney (MK) cells were chosen rather than cell lines or strains in order to study cells as closely as possible to the in vivo state.

Initial experiments were designed to find the dose of BHT which stopped cell numbers increasing. When this had been established a more detailed investigation was carried out to study the effects of this dose on primate cell metabolism by measuring the rate of incorporation of radioactive precursors into DNA, RNA and protein.

Solutions of pure grade BHT, the metabolites 3,5ditertbutyl-4-hydroxybenzoic acid (BHT-acid), 3,5-ditertbutyl-4-hydroxybenzyl alcohol (BHT-alcohol) and αtocopherol were prepared fresh for each experiment by dissolving overnight in dimethylsulphoxide (DMSO). All dilutions were made up to contain 0.9 per cent DMSO with 199 tissue culture medium containing 10 per cent calf serum and antibiotics. For the radioactive precursor studies, solutions containing 0.1 µc./ml. of tritiated thymidine-6-T (n) (3HTdR), 0.1 µc./ml. tritiated uridine-5-T (3 H-UR), and 0.05 μ c./ml. D-L-leucine-I- 14 C (14 C-leucine) were made up in phosphate buffered saline (PBS). Eight day old primary monolayer cultures of kidney cells obtained from 2 yr old rhesus monkeys were treated with 0.25 per cent trypsin at 37° C for 5 min and resuspended in growth medium to the order of 5×10^4 - 10^6 cells/ml. Constant stirring maintained a good suspension while aliquots (4 ml.) were removed and seeded into 2 in. diameter plastic Petri dishes. The cells were grown overnight at 37° C in an atmosphere of 5 per cent carbon dioxide in air.

At time zero the supernatant medium was removed, and the monolayers were covered by 4 ml. of growth medium (controls), 4 ml. of growth medium containing 0.9 per cent DMSO (DMSO controls), or 4 ml. of growth medium containing the required dilution of test compound in 0.9 per cent DMSO (test). All media were prewarmed to 37° C, and duplicate cultures were treated for each estimation. To avoid complications caused by individual animal variation, each complete experiment utilized cells from one animal only. After treatment for the required time intervals, the monolayers were labelled for 20 min at 37° C. They were then washed with ice-cold PBS, treated with versene, collected into test tubes and resus-

pended in a known amount of PBS. The cells in each suspension were counted, and 1 ml. was transferred to a small centrifuge tube for extraction. Perchloric acid (0.2 normal) was used to remove nucleotides from the samples, and the acid precipitated proteins and nucleic acids were dehydrated by two washes of ethanol before rendering them soluble in 0.3 ml. of hyamine at 60° C The hyamine was dissolved in 3 ml. of scintillation fluid containing 0.01 per cent POPOP and 0.4 per cent PPO in toluene and was then pipetted into a counting vial. The samples were counted for 10 min in a Packard 'Tri-Carb' scintillation spectrometer. Precursor (0.8 ml.) was added to 3 ml. of Bray's scintillation fluid13 and c.p.m. were measured for each batch of radioactive precursor prepared. Dividing the c.p.m. of 104 cells by the c.p.m. of the precursor used and multiplying by 100 gave a value proportional to the percentage of precursor uptake into 104 cells. Using this value a direct comparison between different experiments was possible.

The MK cell monolayers were treated with 0.034 mmolar, 0.068 mmolar and 0.136 mmolar BHT for 24 h. Each monolayer was detached from the glass with versene and collected in a test tube, resuspended in suitable known amounts of PBS free from calcium and magnesium ions and counted in a haemocytometer. The percentage inhibition of increase in cell numbers was calculated

according to the equation

inhibition was reversible within a further 24 h. Cells treated for 48 h showed a greater inhibition than those treated for 24 h.

Inhibition of cell numbers may result either from cell death or from a sub-lethal depression of cellular metabolism. MK cells were therefore grown on coverslips and treated with 0.136 mmolar BHT for 24 h and stained with May-Grünwald-Giemsa. There was no apparent morphological difference between the BHT-treated and DMSO control cells when examined by light microscopy.

Three separate series containing test, control and DMSO control cell cultures were labelled with ³H-TdR, ³H-UR or (¹⁴C)-leucine after treatment with 0·136 mmolar BHT for 0.5, 3 and 24 h: male MK cells were used. The rate of synthesis of DNA and RNA was also measured in a repeated experiment using female cells after treatment for 0.5, 1, 3, 5 and 7 h.

Fig. 2 shows that the rate of RNA synthesis was most affected by the BHT, male cells showing 50 per cent inhibition and the female 95 per cent inhibition. In the male cells, protein synthesis seemed to be the least inhibited, decreasing by only 15 per cent. In both experiments, depression was rapid, and was maximal within

A foreign compound may be toxic to an organism in its native form, or as a metabolic intermediate before its

increase in cell No. (DMSO control)—increase in cell No. (test) \times 100 (ref. 14) increase in cell No. (DMSO control)

In other experiments, monolayers which had been treated with $0.136\,\mathrm{mmolar}$ BHT for 24 h were washed with growth medium and grown for a further 24 h in fresh growth medium. Simultaneously, other cultures were treated for 48 h. DMSO controls were treated in a similar

The MK cell numbers showed an inhibition proportional to the concentration of BHT used (Fig. 1). This 24 h excretion 15. Because the metabolism of BHT in the MKcell culture system has not yet been proved. It was felt to be important to test two BHT metabolites for inhibitory effects. Each of three groups of MK cell monolayers were treated with either BHT, BHT-acid or BHTalcohol, at a molarity of 0.136 mmolar. After 1, 3 and 5 h the cells were labelled with 3H-UR and the percentage uptake into RNA, compared with DMSO controls, was

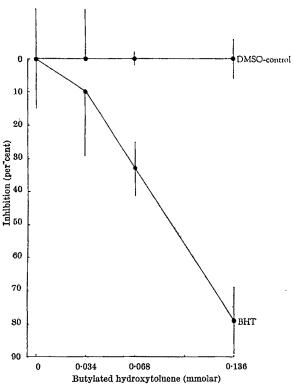

Fig. 1. The percentage inhibition of MK cell numbers after exposure for 24 h to 0.034, 0.068 and 0.138 mmolar BHT (dissolved in 0.9 per cent DMSO in growth medium). Cultures treated with 0.9 per cent DMSO were assumed to show no inhibition. The $95\,$ per cent confidence limits are marked.

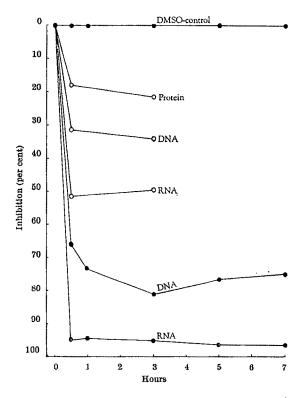

Fig. 2. The percentage inhibition of DNA, RNA and protein synthesis in MK cells treated with 0-136 mmolar BHT. All the values marked were significantly lower than those for the DMSO control. O, Male cells; \bullet , female cells.

calculated. The cells showed little or no significant inhibition of RNA synthesis caused by BHT-acid or BHT-alcohol (Fig. 3).

The possibility that antioxidant activity of BHT induced a metabolic inhibition was tested by comparing the effects of the natural antioxidant α-tocopherol 10,17 and BHT on RNA synthesis. Monolayers of cells were treated with either 0·140 mmolar α-tocopherol or 0·136 mmolar BHT for 0·5, 3 and 24 h, and then labelled with 3H-UR. The results in Fig. 4 show that the α-tocopherol had no significant effect on the synthesis of RNA.

Cells were treated for 1 h with 0·136 mmolar BHT. These cells were then washed with prewarmed growth medium, and grown for a further 23 h in fresh growth medium. At 24 h the same cells were again treated with 0·136 mmolar BHT for a further hour and reversed as before. At each reversal, some treated cultures were left in BHT medium to act as BHT controls. The DMSO control group were treated in a way identical to the BHT group of cultures. Cells were labelled with ³H-UR after 1, 3, 24, 25 and 26 h. The results in Fig. 5 show that a complete and rapid reversal of RNA inhibition occurred after removal of the BHT. In all experiments, the DMSO controls showed only slight, if any, variation from the control results.

In addition to these experiments, a duplicate set of precooled control cells were labelled at $+4^{\circ}$ C for 20 min with 3 H-UR to measure RNA synthesis in cells with a greatly reduced metabolic turnover. These cells showed a 90 per cent inhibition in the synthetic rate when compared with the 37° C controls. A variability in the cellular inhibition caused by 0·136 mmolar BHT was noted in some experiments. This seemed to be correlated with the cell sex; cells from male animals were relatively less affected, and female cells showed a wider range of results. The significant decrease in MK cell numbers treated for 24 h with 0·136 mmolar BHT seems to result from a rapid

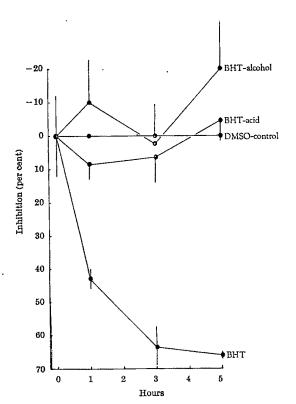

Fig. 3. The percentage inhibition of *H-UR incorporation into MK cell RNA ceused by 0-136 mmolar BHT and the BHT metabolites 3,5-ditertbutyl-4-hydroxybenzoic acid (BHT-acid), and 3,5-diterbutyl-4-hydroxybenzyl alcohol (BHT-alcohol). The 95 per cent confidence limits are given, those of the metabolites and the DMSO control all overlapping.

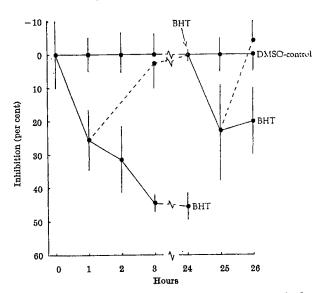

Fig. 5. The reversibility of inhibition of MK cell RNA-synthesis after exposure to 0·136 mmolar BHT for 1 h. The reversed cells were re-treated for 1 h with BHT at 24 h, and again reversed. 95 per cent confidence limits are shown. ————, Reversed cells in growth medium.

depression of DNA, RNA and protein synthesis which would result in a lowered mitotic index¹⁸.

BHT is a highly lipid soluble compound¹⁹, and thus will associate with the lipids of the plasmalemma and the intracellular membrane systems. If this lipid association were to cause configurational changes^{20–22} in biochemically active and/or structural components of the membrane, for example, by altering the membrane water structure²³, then it might interfere with the normal metabolic systems situated partially or wholly in these membranes^{24–26}. Here it is

important to note that two BHT metabolites, 3,5-ditertbutyl-4-hydroxybenzoic acid and 3.5-ditertbutyl-4hydroxybenzyl alcohol, both hydrophobic compounds, did not cause inhibition of RNA synthesis at concentrations of 0.136 mmolar. This difference may be the result of a specific characteristic of the molecule-BHT or, alternatively, of a more rapid excretion of the metabolites.

The capacity of various compounds to prevent oxidation has been measured by the AOM, or "active oxygen method"²⁷. α-Tocopherol has a recorded AOM value of 83, compared with 67 for BHT and 23 for unprotected controls2. In the experiments reported here, however, 0.14 mmolar α-tocopherol does not inhibit RNA synthesis comparable with that produced by 0.136 mmolar BHT, despite its hydrophobic nature and similar antioxidant activity.

The in vivo metabolism of BHT has been studied in rats and rabbits^{6-8,28}. This occurs chiefly in the liver, involving the enterohepatic circulation^{7,29}. The capability of MK cells to metabolize BHT in vitro has not been proved. In both the cell number and labelling experiments, however, the depressions induced by BHT were rapidly reversed by removal of the BHT, and this may be caused by the MK cells converting BHT into non-inhibitory metabolites. A variation in results seemed to be correlated with cell sex; male cells were usually less affected by the BHT than were the female cells. The possibility of BHT being more rapidly metabolized in the male MK cells arises. In vivo, the hydroxylating activity of the liver in untreated rats is greater in males than females³⁰; also Catz and Yaffe³¹ have shown that hexobarbital sleeping times in female rats varied with the oestrous cycle. The concentrations of BHT permitted for use in such

foods as butter, lard and margarine is 160-200 p.p.m., and 1,000 p.p.m. is allowed in essential oils³². In vivo oral doses of 500 mg of BHT/kg body weight cause an increase in the relative liver weight of rats33. In these experiments, 0.136 mmolar BHT, or 30 p.p.m., caused an inhibition of cellular metabolism, leading to a relative fall in cell numbers, in 4×105 cells, weighing approximately 46 mg. Although this in vitro dose is relatively high, it is difficult to make a direct comparison with the in vivo experimental results because of the different effects measured. Also, selective concentration of oral doses of BHT may occur in vivo, such as in the small intestinal

wall during lipid absorption34 and in the liver during metabolism.

I thank Dr R. Borland for his valuable criticism, Dr F. Perkins (MRC Laboratories) for the monkey kidney cells and Dr A. S. Wright for the BHT metabolites. This work was supported by a Nuffield Foundation food safety research scholarship.

Investigation of Pre-Cambrian Thucholite

by

ALEXANDER A. PRASHNOWSKY

Geologisch-Palaeontologisches Institut, University of Würzburg, Germany

MANFRED SCHIDLOWSKI

Geologisch-Palaeontologisches Institut, University of Göttingen, Germany

Biochemical identification of amino-acids and monosaccharides in carbonaceous materials from the Witwatersrand indicates that there was life in Pre-Cambrian times. Electron micrographs of surface replicas of the surrounding rocks also suggest a probable organic derivation of these carbon concentrations.

THE occurrence of vast amounts of carbonaceous matter or thucholite in the gold-uranium conglomerates of the South African Witwatersrand System has intrigued geologists for a long time, although a systematic mineralogical investigation of these substances was not attempted until 1951 (ref. 1). Earlier this year Hoefs and Schidlowski2 presented isotopic data which seem to support a biological derivation of these carbon concentrations. From the range of the δ^{13} C values (-22 parts per thousand to -33 parts per thousand), it was concluded that photosynthetic processes were operating in those times, bringing about an accumulation of the source material of the polymerized hydrocarbons which now make up the bulk of the carbonaceous matter. Because the sedimentation of the Witwatersrand System was complete about $2\cdot15\times10^9$ yr ago³ it seemed probable that there was a flourishing primitive life in early Pre-Cambrian times. This assumption has recently been substantiated by the discovery of cell-like structures within Witwatersrand rocks⁴ as well as by the occurrence of primitive life forms in strata of a comparable or even older age⁵.⁶. With these preliminary results at hand, the launching of both a biochemical research programme and an electron microscopic investigation seemed to be warranted, the first results of which are communicated in this paper.

Biochemistry of Rock Samples

Amino-acids and carbohydrates were singled out as the primary objects because they are usually synthesized by, and therefore indicative of, life processes. The analytical technique applied for the identification of amino-acids consisted of one or two dimensional descending paper chromatography using a set of different buffered solvents? with a following quantitative colorimetric determination by means of a Beckmann spectral photometer. Carbohydrates were separated by one dimensional descending paper chromatography; the quantitative determination was again colorimetric. A detailed description of the laboratory technique has been given elsewhere.

per cent. Another important group is represented by the sulphur-bearing amino-acids accounting for 20-9 per cent.

In the quartzite rock close to the carbon-rich "B" Reef, cystine and methionine are the most abundant amino-acids, and these sulphur bearing compounds make up nearly 50 per cent of the total amino-acid content of the rock. Tyrosine is another conspicuous constituent of this sample. On the other hand, the quartzite adjacent to the Basal Reef shows a marked preponderance of the oxymonoamino-monocarboxylic acids serine and threonine (31.9 per cent), with tyrosine again occupying the third place in the order of abundance. Altogether, it is obvious that the quartzite samples as well as the carbonaceous matter contain aliphatic amino-acids in excess of aromatic amino-acids; the heterocyclic acids have not been determined in this first set of analyses. Furthermore, it cannot be overlooked that the sulphur-bearing amino-acids are well represented in all samples investigated, accounting sometimes for nearly 50 per cent of the total yield. This seems to emphasize the important role of sulphur in the physiology of primordial life.

In addition to amino-acids, several carbohydrates were recovered from thucholite samples in amounts ranging from 10-26 p.p.m. Seven monosaccharides have been quantitatively determined (Table 2). Among the hexoses, mannose and glucose are the prevalent components, whereas among the pentoses, wood sugar (xylose) plays

Table 1. Amino-acid content of three samples of carbonaceous matter and two samples of wall rock quartzite occurring adjacent to carbon bearing conglomerate horizons or reefs

Sample	Reef	Mining company	δ ¹³ C of carbon in parts per thousand				Aliphatic amino Oxymonoamino- monocarboxylic acids		o-acids Monoamino- dicarboxylic acids		Sulphur bearing amino-acids		Aromatic amino- acids

Thucholite Thucholite Thucholite Quartzite Quartzite	"B"-Reef Basal Reef Basal Reef "B"-Reef Basal Reef	Loraine Virginia Virginia Loraine President	-27·1 -22·4 -22·9	6·6 3·5 6·6 5·7 7·4	9·7 5·8 7·3 6·9 4·0	8·8 3·8 5·7 5·0 3·8	$\frac{-}{13.7}$ $\frac{13.7}{20.8}$	11·6 12·0 17·5 7·9 11·1	13·8 9·9 8·0 8·8 9·5	5·2 3·7 8·9 5·8 8·2	2·0 21·4 10·3 16·7 13·5	19·3 14·6 10·6 29·6 7·5	28-0 25-2 11-3 13-5 14-2	100-0 99-9 99-9 99-9 100-0

The figures represent the percentage (dry weight) of the single compounds within the sample.

Table 1 shows a compilation of amino-acids isolated from three thucholite and two quartzite samples, the latter having been taken from the immediate wall rock portions of thucholite-bearing conglomerates. The applied subdivision has been adapted from Meister. The total content of amino-acids within the carbonaceous matter ranges from a minimum of 2 p.p.m.-20 p.p.m.; the respective values of the quartzites are considerably lower (0.8-3 p.p.m.). Whereas the lowest values lie in the range of a possible contamination, the upper ones should be high enough to exclude such a possibility. An evaluation of the percentage distribution of the individual aminoacids shows that in the first thucholite sample, tyrosine, an aromatic amino-acid, is the most abundant component, accounting for nearly one-quarter of the total amino-acid content. Cystine, a sulphur bearing aminoacid, takes the second place and is followed by aspartic acid. Among the single groups of amino-acids, the monoamino-monocarboxylic acids make up about 25 per cent of the bulk content, while the sulphur-bearing amino-acids are next with 21.3 per cent. The second thucholite sample also shows a predominance of tyrosine (25.2 per cent) among the single compounds, whereas the most important group is represented by the sulphur bearing amino-acids (methionine and cystine) which together amount to 36 per cent. Within the third thucholite sample, threonine takes the lead with 17.5 per cent, other important components being serine (13.7 per cent) and tyrosine (11.3 per cent). This sample is, accordingly, characterized by a preponderance of the oxymonoamino-monocarboxylic acids, serine and threonine, together constituting 31.2

Table 2. CARBOHYDRATES FOUND IN CARBONACEOUS MATTER

	Hexoses						
Galactose	Glucose	Mannose	Arabinose	Xylose	Ribose	Rhamnose	
13.47	19.12	20.60	11.83	14.06	8.59	12-29	99-96

Values are an average for four samples. The figures give the percentages (dry weight) with which the individual compounds are represented in the total yield. The samples are derived from the "B" and Basal Reefs (Loraine Gold Mines, President Brand, Western Holdings).

the most important part. The hexoses constitute the principal group, being about 53 per cent; the pentoses are probably more liable to decomposition and therefore slightly under-represented in the fossil record.

Significance of Results

Biochemical investigations thus strongly support concepts advocating a biogenic derivation of the carbon assemblages which had already been advanced earlier from geological considerations1, putative micropalaeontological evidence4 and from carbon isotope data2. In our opinion the presence in Witwatersrand rocks of aminoacids and monosaccharides can only be explained if life processes operated in those times. Although several workers have pointed out that some amino-acids may be produced abiotically 10, this possibility can be precluded in this case. The early period in the history of the Earth which was possibly characterized by an abiotic production of amino-acids must have been terminated before 3.1×10^{9} yr ago, for organized organic relics of this age have been recently reported from other South African rocks. Moreover, an abiotic synthesis of monosaccharides under primi-

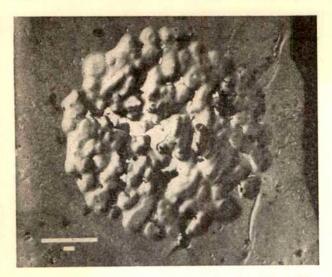

Fig. 1. Electron micrograph of a surface replica taken from a Witwatersrand quartzite neighbouring the Basal Reef. The globose aggregate depicted resembles a cell colony. The scale represents 5μ (long line) and 1μ (short line), respectively.

tive earth conditions appears extremely unlikely. A large scale contamination of the Witwatersrand rocks with these organic chemicals during their post-depositional geological history is also very unlikely, for the compounds are not only restricted to the carbon assemblages (the parent hydrocarbons of which took part in a limited migration, although their source material was certainly indigenous to the sequence), but are also locked up in ordinary quartzite.

Survival of Organic Compounds for a Very Long Time

We have reason to assume that the amino-acids and carbohydrates described originated in their present milieu, and so they must have been preserved-in spite of their intrinsic instability—for more than 2.15 × 10° yr. Although both amino-acids and carbohydrates are well represented in the fossil record down to the Cambrian8,11,12, their occurrence in early Pre-Cambrian rocks must necessarily raise suspicion, even if these rocks have had only a mild thermal history. This suspicion is in particular nourished by the fact that among the amino-acids described are compounds like serine, threonine and tyrosine which have been regarded as relatively unstable by Abelson¹¹. The presence of amino-acids, however, has been reported from other Pre-Cambrian sediments which are only slightly younger than the Witwatersrand System13; furthermore, the putatively unstable compounds serine and threonine have been isolated from rocks at least 1.95 × 109 yr old14. Experimental work on the thermal stability of aminoacids carried out recently has shown that this stability depends largely on environmental factors. For example, in a fine mixture with montmorillonite, amino-acids like cystine, glutamic acid, methionine and leucine may sustain temperatures between 300° and 400° C for about 170 h, although the fusing points of the pure substances (which coincide with the temperatures of disintegration except in the case of glutamic acid) lie at 258°, 225°, 283° and 294° C, respectively15. One should therefore hesitate to extrapolate from the behaviour of the pure substances in vitro on their behaviour in the sediment where the material occurs in a finely dispersed form allowing interactions with other components which might possibly result in a protective effect. It is outside the scope of this preliminary communication to deal at length with all aspects of this problem; in the present stage of the investigation we prefer to present the mere facts, even if the latter are—at least at the moment—difficult to reconcile with certain theoretical considerations. As carbonaceous material from the Witwatersrand is not difficult to

obtain, the reliability of our results can be easily checked by other workers.

Electron Microscope Techniques

In view of the startling results of the biochemical investigations, a systematic search for structurally preserved remnants of early life in the surrounding rocks seemed very promising. Ordinary microscopy had yielded only scanty hints at probable life forms and the application of the electron microscope therefore seemed necessary. This approach was in particular prompted by the fact that electron microscopic techniques have just recently proved to be of outstanding value for palaeontological work on Pre-Cambrian micro-organisms 6,16.

In our attempt to examine the surfaces of quartzite samples from the Witwatersrand System, we followed standard procedures. A relatively even fracture plane of the rock was covered with either a 'Formvar' or 'Technovite' film which was stripped off after polymerization and then shadowed with platinum and replicated with carbon in a vacuum evaporator. The resulting platinum-carbon film was liberated from the underlying 'Formvar' (or 'Technovite') layer in a chloroform bath; the platinum-carbon replicas were washed in acetone and distilled water and finally mounted on microscope grids.

Figures 1-3 show some electron micrographs of surface replicas of samples of Witwatersrand quartzites taken from near carbon bearing reefs. The objects illustrated suggest a probable organic derivation. This applies in particular to the peculiar aggregate resembling a cell colony (Fig. 1), each of its individual elements displaying a characteristic small central hub which might be explained as the nucleus of a shrunken cell. Other cell-like structures are depicted in Fig. 2. The forms at first seem to resemble elongated bubbles, but indications of a certain regular branching cannot be overlooked. It is conspicuous that they are mostly arranged in one preferred direction which coincides with a crack system within the rock. Sometimes the individuals form chain-like aggregates Whether elements like these are actually of biological origin or rather constitute vacuoles within a quartz grain is very difficult to assess at this early stage of the work; we think it advisable, however, to present these forms here in order to bring them to the attention of, and have them discussed by, other

The electron microscopic as well as the biochemical work is being continued and a further report will be given later. Overall, the preliminary results are encouraging, thus corroborating the idea of a high diversity of primordial

Fig. 2. Peculiar elements resembling open, elongated bubbles. Some of them, however, exhibit a kind of branching, thus raising suspicion of an organic derivation (from Witwatersrand quartzite as in Fig. 1; the line represents 1μ).

life which has been stressed in recent reviews on Pre-

Cambrian palaeontology¹⁷.

We thank Professor F. W. Schlote, Mr R. Dierichs, Mr K. H. Matucha, Mr J. Petermann, Dr J. Pense and

Mr M. Danai for their help. Note added in proof. According to a personal communication by Professor F. M. Swain to one of the authors, amino-acids have meanwhile also been recovered from rocks of the Fig Tree Series (>3×10° yr old) of the Barberton Mountain Land, South Africa; the respective results are not yet published. These findings most decidedly substantiate the data presented in this paper. On the other hand, Kranz¹⁸ has recently advanced the hypothesis that amino-acids may be synthesized abiotically by radioactive irradiation of traces of ammonia and simple alkanes (like methane) which are sometimes present in several minerals and rocks. Even if this concept should prove true, it cannot account for the occurrence of monosaccharides within the carbonaceous material, for the origin of which life processes are a necessary postulate.

Ice Nucleation and the Substrate-ice Interface

by

DUWAYNE M. ANDERSON

Division of Physical Chemistry, Royal Institute of Technology, Stockholm US Army Cold Regions Research and Engineering Laboratory, Hanover, New Hampshire

Embryo crystals form by enlargement of one of the normal components of the liquid. This is favoured by reduced molecular motions and a tendency towards more open, hydrogen bonded regions near the interface.

THE heterogeneous nucleation theory, as it is usually expounded, is based on the probability that an embryo crystal forms on the surface of a substrate and grows, by statistical fluctuations, to a critical size beyond which the radius of curvature of some portion of its surface is large enough to favour continued growth to a macroscopic size. In the case of ice nucleation, it is common to visualize that the embryos are attached to the substrate surface where they form a dome of water molecules in which elements of the ice lattice can be identified. It has often been supposed that in order to enhance the probability of embryo formation, a good ice nucleating agent, besides providing a base for embryo formation, should also have certain surface features that match configurations which can be identified in the ice lattice.

The possibility that the water adsorbed by montmorillonite and other clay minerals exists in a more or less rigid, hydrogen-bonded, icelike structure has been suggested by Hendricks and Jefferson1 and Macey2. Soon after this possibility was pointed out, investigations to determine the relative water nucleating efficiency of these and similar substrates were made3,4. Although it was shown that the clay minerals are common nucleators, it became clear that they are not as effective as one might expect if they are coated with a layer or patches of adsorbed water in an icelike form. For this and other reasons, it is now generally accepted that good nucleators need not actually constitute a template for embryo growth, but it is still believed that embryo nuclei form by direct attachment to the substrate. This need not be so. There is reason to believe that with some, and perhaps many, substrates, embryo nuclei form and induce nucleation at a location some distance removed from the substrate surface. Direct contacts with the surface, if they exist at all, are probably never more than tenuous and transitory.

Unfrozen Water in Frozen Mixtures

The existence of substantial quantities of unfrozen water in frozen, clay mineral-water mixtures was first indicated by dilatometric and calorimetric measurements^{5,6}. The results are not entirely conclusive, however, for they may be interpreted in two ways. They are consistent on the one hand with a rigid surface layer, tightly constrained by adsorption forces and cannot be melted or, on the other hand, with a liquid-like layer which because of the presence of exchangeable cations and solutes expelled by growing ice crystals, cannot be frozen. Tabor believed that the unfrozen water forms a mobile surface layer separating mineral surfaces from ice through which water transport to growing ice lenses can occur, and he used this concept successfully to explain the phenomenon of frost heaving. As will shortly become evident, this is the correct view. The amount of unfrozen water present in a frozen sample is usually high for materials which have high specific surface areas and low for those that have low specific surface areas, other factors being equal. According to my own unpublished results, although the unfrozen water content changes with solute content in what seems to be a systematic way, it is practically independent of the ice content. The most important factor, however, is temperature; this is well illustrated in Fig. 1 (ref. 8).

The microscopic mobility of the unfrozen water has been established beyond doubt. Hoekstra⁸ has, for example, recently confirmed earlier reports^{9,10} that the conductance of frozen clay mineral-water mixtures is much higher than that of ice at the same temperature and has demonstrated that the data are best explained by postulating continuous pathways in the frozen specimen through which exchangeable cations and other charge carriers can move. Because the exchangeable cations are constrained by electrical forces to regions close to the mineral surfaces and because solutes expelled from growing ice crystals are also expected eventually to concentrate near these interfaces, it is safe to conclude that at least some of the pathways for electrical conduction are to be found in the unfrozen, interfacial water. Furthermore, nuclear magnetic resonance (NMR) measurements on a variety of minerals at temperatures far below the normal freezing point of water have revealed the very high proton mobility (compared with that in the solid state) of the water in close proximity to the mineral surfaces^{11,12}. The fact that electrical and

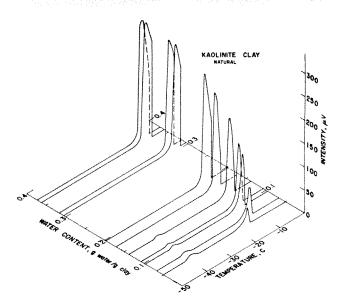

Fig. 2. Graphical summary of results obtained from differential thermal analysis of the kaolinite-water system. Exothermic processes give positive peaks.

thermal osmosis of water is easily accomplished in frozen earth materials demonstrates that the interfacial water molecules possess high mobilities relative to that in ice6,8. The migration of mineral particles suspended in ice, however, offers the most impressive evidence of the fluidity and the continuity of the interfacial water. Corte showed that small mineral particles and glass beads tend to be rejected and pushed ahead of an advancing ice interface when the rate of interface advance is slow and controlled13. Even when the particles become engulfed by ice, subsequent particle migration in response to temperature gradients has been observed and measured14. Migration velocities exceeded 5µ/h at temperatures very near 0° C but amounted to only about $1\mu/\bar{h}$ at temperatures a few tenths of a degree lower. A reason for the decrease can be seen from the data of Fig. 1; near 0° C, decreasing the temperature by a few tenths of a degree markedly reduces the thickness of the unfrozen water layer. migration almost certainly involves the melting of ice in front of a particle and the transfer of water through the unfrozen interfacial zone to the rear where it refreezes. Closer confinement because of a decrease in thickness of the unfrozen interfacial zone brought about by a decrease in temperature must therefore cause a reduction in the particle migration velocities.

Low Temperature Analyses of Clay-Water Systems

The interfacial layer is seen to be many molecular diameters thick at temperatures near 0° C and never seems to be less than one or two molecular diameters thick down to -10° C and lower. Decreasing the temperature probably also causes a decrease in the mobility of the interfacial water. A temperature dependence of this kind is most obvious in the particle migration velocities very near 0° C; it is also obvious in the electrical conductance measurements down to about -20° C. Large decreases in proton motions, however, begin to be evident in the NMR data only at about -80° C. order to locate phase transition temperatures and to define fruitful temperature-pressure fields for more precise calorimetric investigations of interfacial phases, we have made some systematic low temperature differential thermal analyses of representative clay-water systems together with ancillary theoretical studies. Some DTA data bearing on this discussion are summarized in Figs. 2 and 3. The data were obtained as follows. The clay-water contents were fixed at desired values and after a lengthy equilibration period a sample was packed into the DTA cell. The cell and its contents were then cooled at a controlled rate and a continuous recording was made of the cell temperature and temperature differences between the sample and the cell wall. The magnitude of the temperature difference (signal intensity) between the sample and the DTA cell is given in microvolts (positive values correspond to exothermic processes as the temperature was lowered).

The first exotherm quite obviously corresponds to the heat evolved on initial freezing of the sample. The intensity of the exotherm diminished with diminishing water content in accord with expectation. Allowing for a few degrees of undercooling, it can be shown that the lowering of nucleation temperature with diminishing water content (decreasing interfacial water thickness), apparent in Figs. 2 and 3, seems to follow the law of the freezing point lowering. This suggests that embryo formation is dependent on the thermodynamic activity of the interfacial water relative to that of ice, but it can be seen that even at high water contents before nucleation occurred, as was observed earlier. It was necessary to undercool the sample 4° or 5° C.

It can be seen that additional exotherms were detected at lower temperatures. For water contents corresponding roughly to monolayer coverage of the mineral surface and above, these exotherms did not vary markedly with water content and they seem to be distinctive of elay lattice type. The low temperature exotherms were not observed in black runs. Neither were they observed with ice alone or with completely dry clay. It may be concluded therefore that they result from phase changes in the temperature range where evidence at present available suggests that the molecular mobility of the unfrozen, interfacial water becomes very low. It is probable that these exotherms correspond to the development of structural rigidity in the unfrozen, interfacial water. configuration and nature of the structures developed cannot be deduced from the evidence available, but there is sufficient difference evident from Figs. 2 and 3 to sug-

Barting a language second by

gest that the structures finally frozen into the interface are different for each substrate. Montmorillonite crystals have both internal and external surfaces exposed to water, whereas kaolinite crystals have only external surfaces. Two low temperature exotherms were observed in mentmorillonite—water systems but only one was observed with kaolinite. One wonders if the exotherm common to both, that at about -39° C, corresponds to the interfacial water on external surfaces. If so, one would then associate the exotherm at about -48° C with structural changes in the interlamellar water of montmorillonite. There is also the possibility, however, that ion dehydration occurs at some point, and that this also contributes to one or both peaks.

In the case of kaolinite, the low temperature exotherm was not observed at water contents exceeding about 0·15 g of H₂O/g of clay. In the apparatus used, the sample size was small (about 5 g) and fixed, so that increasing the water content required a corresponding decrease in the amount of clay present. This in turn resulted in a decrease in quantity of the interfacial water present. At high water contents it is likely that the amount of interfacial water present in the kaolinite-water system became too small to produce a detectable signal. The specific surface area of montmorillonite is about ten times greater than that of kaolinite so that one would only expect the same effect in montmorillonite above about 1·5 g of H₂O/g of clay. This explains why the low temperature exotherms were observed in the montmorillonite-water system at the highest water contents examined.

Nucleating Phenomena

From these results, it seems beyond doubt that in frozen silicate mineral-water systems, the ice crystals are separated from the substrate surface by an unfrozen, fluid-like interfacial zone of water. Considerable fluidity of the interfacial water seems to persist at temperatures at least as low as -10° C; at about -40° C, rigid structures begin to be frozen in. At temperatures near 0° C, the unfrozen interfacial zone is many molecular diameters in thickness and the ice, except possibly for temous and transitory links, cannot be directly bonded to the substrate. In these circumstances, to say that ice nucleation is caused by embryo crystals forming by direct attachment to the substrate and subsequently growing to a size sufficient to nucleate the surrounding water becomes highly questionable.

Many points of similarity in nucleation phenomena induced by organic and inorganic substrates may be pointed out. Space does not permit a full consideration, but one example will suffice to illustrate the point. Evans has reported the results of ice nucleation studies at high pressures involving phloroglucinol dihydrate and some other organic substrates17. He observed that the undercooling required for nucleation was usually about 6° C at atmospheric pressure but became nearly zero at 1,500 bars and higher. This was true of only the first nucleation, however; on melting, if the sample temperature did not exceed +1° C, something less than the original undercooling was required at all pressures. This "memory effect" was attributed to the development of stabilized water structures on the substrate after freezing in which monolayer patches of ice could grow and subsequently serve as nucleation sites. (The possibility of imprinting the ice structure on the substrate itself was considered and rejected for what seem to be good reasons.) Because the temperature at which memory is erased was found to be $0^{\circ} \pm 1^{\circ}$ C regardless of the pressure, Evans argued from the Clausius-Clapeyron equation that the volume change accompanying deactivation of memory in the adsorbed water must be very small and concluded that the only way in which this could be so is for the water structure at the nucleation sites to consist of a single |0001| layer of ice (a second layer would reduce the density of this layer too much) on the substrate surface.

Icelike structures for water absorbed on clay substrates have been proposed on several occasions. It has been shown, for example, that the density of the interfacial water immediately adjacent to montmorillonite surfaces is some 3 per cent less than that of the normal liquid but that it is substantially greater than that of ice18-20. Furthermore, at atmospheric pressure, about 5° C undercooling is frequently necessary to accomplish spontaneous nucleation with silicate substrates, and a memory effect for these substrates similar to that observed by Evans for organic substrates was mentioned recently by Graham et al. 12. Mineral substrates tend to be rejected from growing ice crystals, and frost heaving on a microscopic scale is commonly observed when biological materials are frozen. In all probability, it will soon be demonstrated that, depending on temperature, a liquid-like, interfacial zone of unfrozen water also separates ice from the surface of many, if not all, organic

It may be awkward, but not impossible, to reconcile the idea of embryo formation and growth on the substrate surface with the fact that the ice subsequently formed is, except for possible sporadic, tenuous links, completely separated from the substrate. It seems far more likely that although embryo formation may be induced, and embryos in a sense may be stabilized by the interaction of fluids with substrate surfaces in such a way as to favour further growth, the formation and growth of embryos actually occur at a location several, perhaps many, molecular diameters distant from the substrate. After nucleation and freezing, as the temperature falls the unfrozen interfacial zones must diminish in thickness, and when the temperature is later raised the interfacial zones must be thickened because of the progressive melting back of the ice interfaces, in general accordance with the relationships shown in Fig. 1. The memory effect is explained by the fact that active nuclei may be stabilized by the environment of the interfacial region and even after melting is complete they may remain in certain favourable locations. The size, and hence the potency of these "protected" nuclei is determined by the maximum temperature to which they are exposed.

The concept introduced here is in some respects similar to a theory of heterogeneous nucleation advanced by Dorsey21. He visualized an adsorbed layer of liquid orientated by influences from the substrate and from which small aggregates might be dislodged as a result of molecular collisions or shearing forces. He thought it was likely that some of the aggregates torn loose from the adsorbed layer would be larger than critical size at some temperature below the normal freezing point, and these, possibly by reorientation or further growth, would eventually become viable nuclei. The interface envisaged in his theory is characterized by a relatively strong binding of the absorbant to the substrate which diminishes in intensity in progressively distant adsorbed layers until the state of the bulk liquid prevails. The aggregates are supposed to be dislodged from the outermost layers by molecular collisions or by mechanical shearing. The idea that nuclei formed in this manner could, in the interfacial environment, be stable until heated to the melting point of the solid phase is more or less implicit in Dorsey's theory, and in this respect his theory can be said to accommodate earlier explanations advanced to explain memory effects when a melt is refrozen²².

Formation of Embryos

The theory advanced here requires the stabilizing presence of a substrate but does not require embryo attachment to the substrate, nor does it visualize embryos as being torn out of an extended network of molecules

existing in an ordered array next to the substrate. What is proposed here is that various kinds of ordering are brought about in water by interaction with a substrate and that these may be identified and characterized in localized domains in the interfacial zone. The location and extent of these domains must shift in special ways as the temperature is raised or lowered. Thinking in terms of the "flickering-cluster-mixture-model" of water, at some favourable location in the interfacial zone sufficiently removed from the intense—and perhaps too specificinteractions at the substrate surface, an environment exists in which the lifetimes of icelike flickering clusters are lengthened appreciably. This requires an increase in the coherence and extent of hydrogen bonding of the clusters which in effect creates embryos and facilitates their enlargement by molecular accretion into nuclei. Embryos can thus be said to form by enlargement of one of the normal components of the liquid. The critical aspects of the environment created by the substrate which favour embryo formation no doubt involve reduced molecular motions and a tendency towards more open, hydrogen bonded regions near the interface. Viewed in this way, heterogeneous nucleation is satisfying similarly in concept to homogeneous nucleation. The effect of a substrate is simply to provide a protective environment in which nuclei of critical size may form in the same way but at a temperature substantially higher than that required for embryo growth to similar size in the pure liquid. Once formed, these icelike clusters can easily be incorporated into the ice and on subsequent melting many may remain intact and active at favourable locations in the interfacial zone, provided the temperature is not raised too far above the melting point; hence, subsequent freezings may require little or no undercooling.

This theory of heterogeneous nucleation can account for all the experimental observations so far reported, including those of Evans made with organic substrates. It is also in harmony with the observations that silicate substrates when completely engulfed by ice are nevertheless free of direct attachment to the ice. Although considerably more work may be required to establish its validity, the concept I have advanced is attractive and promises to be useful. One of its most attractive features is its stress of the basic similarity which may exist between the homogeneous and heterogeneous nucleation theory as it applies to water.

LETTERS TO THE EDITOR

ASTRONOMY

Energy Emission from a Neutron Star

Although there are still many problems concerning the supernovae, there is little doubt that a very dense stellar core has to be left behind after the explosion (at least in some cases). During the contraction of this core, inverse β reactions take place and transform most of the nuclei and electrons into neutrons. If the mass of the neutron star does not exceed a critical value of about one or two solar masses, a stable equilibrium situation can be reached with the gas pressure balancing the gravitational force.

A newly formed neutron star is an excited object. Apart from its thermal content (which will be dissipated very fast because of neutrino processes), there will also be much energy stored in vibrational and rotational form. The problem therefore arises of finding out whether the energy stored in the neutron star plays an important part in connexion with the activity observed in some supernova remnants such as the Crab Nebula.

The vibrations of the neutron star, however, do not last long enough for our purposes. The principal reason for this is that the emission of gravitational waves will damp quadrupole and higher order pulsations in a few seconds (ref. 1 and unpublished work of T. A. Wheeler and A. Zee). Moreover, because the stellar rotation will mix the radial modes of vibrations with the non-radial one, all the vibrations are going to disappear very quickly.

It seems more rewarding therefore to look for some mechanisms by which the neutron star can release either its magnetic or its rotational energy or both. In this communication I would like to outline the principal features of a possible model of this kind.

The existence of very strong magnetic fields in the neutron stars has been suggested as a consequence of the compression of an ordinary stellar field. The underlining assumption here is that the conductivity, σ , of the stellar matter is so high that the decay time for the field exceeds the collapse time. As the collapse time is of the order of seconds, this means

$$\tau_{\rm decay} \sim \frac{4\pi \, \sigma R^2}{c^2} \gg 1$$
(1)

where R is the radius of the neutron star (about 10^6 cm). For any conceivable value of σ this is a very weak requirement. We can therefore expect the field strength to increase as $1/R^2$ during the contraction so that fields as high as $10^{10}-10^{14}$ gauss can be produced².

If we assume that the magnetic field is that of a dipole, the angle between the dipole and the angular momentum is likely to be arbitrary (oblique rotator). Actually, even if the two axes coincided in the pre-supernova star, the mass loss occurring during the explosion is unlikely to be perfectly symmetric, especially in the presence of strong magnetic fields. The mutual inclination of the two axes will then be modified and both the rotation and the magnetic field will tend to flatten the star (but along different directions). The shape of the star is going to be rather complicated and the body will rotate about an axis which is not a principal axis of inertia. This is a non-equilibrium situation and the motion will be such that the total angular momentum is constant while the
